T. P. Lowe, found a dislocation of the bones of the forearm backwards, with protrusion of the humerus through a wound about four inches long, oblique to the axis of the limb, in front of the elbow, and the main vessels torn across. These last Mr. Lowe tied with carbolised catgut, then closed the wound with sutures after carbolising it thoroughly, enveloping the injured part in a Lister's gauze dressing. The limb being cold and pulseless, Mr. Parker was sent for to decide the question of amputation. On his arrival, an hour or so later, the limb was warm again, though naturally pulseless at the wrist. The injury was exposed under the spray of carbolic acid, and as some blood was oozing from the wound the stitches were removed. The tied stump of the brachial artery was seen pulsating; a small bleeding branch was tied, and the nature of the dislocation was re-examined. On extending the elbow the forearm bones immediately slipped backwards, leaving the humerus freely exposed. This bone was stripped of all muscular attachment for the lower three inches of its length, and the articular surface had a pink colour from blood-staining. In the acutely flexed position the humerus remained properly locked in the sigmoid notch of the ulna, while the latter carried the radius in normal attachment to it. It was decided to preserve the limb, and so the dressings were reapplied, but the wound was not sewn again, being left to fall together without tension in its deep parts, with the skin aperture gaping. The dressings were changed daily for five days, no drain being used on the day of injury. On the second day a piece of folded gutta-percha tissue was passed down to the bone, by forcing asunder the already adherent textures, and retained for a day or two, but it seemed afterwards that it might have been dispensed with altogether. However, it was put in to prevent retention of fluid in the deep parts of the elbow. After five days the wound appeared merely a superficial sore, somewhat over three inches long, and perhaps an inch wide in the middle. The deep parts were adherent by first intention, and nothing but blood, and subsequently serum, escaped into the dressings. Oil-silk protective was laid on the exposed surface on and after the second day, and suppuration was successfully avoided throughout. No splint at any time was used. The wrist was slung to the neck and no difficulty experienced in keeping the limb fixed to the side, in the acutely flexed position, well enveloped in Lister's dressing. By the end of five days she could, when asked, move her fingers freely, a fact suggesting that the muscles stripped from the condyles of the humerus had regained some sort of attachment. Perfect rest was, however, maintained throughout, and no other movements, either active or passive, were permitted. The wound was entirely healed in less than four weeks, during most of which time she was kept in bed. At the end of this period she persisted in going out for a day, in spite of all entreaty to refrain, the arm being still slung at rest to her side. The same night she returned in a state of helpless intoxication, notwithstanding a faithful promise not to incur that condition. The elbow was not a bit the worse, and she left the hospital a few days later, less than five weeks after receipt of the injury. By this time she could move the elbow freely when it was released for the purpose, within a moderate extent of its range, but she was advised to continue the sling for a time. She was not seen again until shortly before a meeting of the Medical Institution on Jan. 31st, 1884, at which she appeared showing perfect performance of all the movements of the joint, up to complete extension and flexion, with no trace of alteration, except a white linear scar, indicating the site where the skin had been severed. At the time of injury the patient was a full-blooded robust woman, of good physique in every way; but she was now thinner, and suffering from a cough that resulted, in the opinion of her friends, from persistent dissipation.

Remarks.—The principles concerned in the management of this case are:—(1) The appreciation of the emergency; (2) the antiseptic treatment of the wound, and the details arising out of its lacerated soft parts and the complete dislocation of the joint; and (3) the mechanical attainment of rest at the elbow-joint. (1) Either compound dislocation or division of the main artery and vein is alone a source of danger to the vitality of the limb beyond, especially if the collateral circulation be clogged by bruising or by subsequent collateral inflammation, as happens under septic irritation. The potential danger to the limb's vitality may be said to have been doubled by the combined injuries. These were truly severe; but although the lacerations were wide and deep, the soft parts not torn were neither bruised nor greatly disturbed, so the warmth and colour of the pulseless limb observed at the second dressing on the day of the accident indicated that the channels of collateral circulation would probably prove sufficient if not subsequently interrupted. The prompt disinfection and protection of the entire wound, effected by the foresight of Mr. Lowe, materially contributed to the grounds upon which the attempt to save the limb was hopefully made. (2) In addition to the double washing with carbolised fluid, the deliberate avoidance of sutures is an important item in similar cases. In a lacerated wound of muscles and fasciæ the freer the opening in the skin the better for access to arrest bleeding and apply antiseptics; the better also for the unrestricted escape of subsequent discharge. The absence of all mechanical tension from the injured soft parts removed a potent source of irritation and consequent ooze of fluid. On the second day there was adhesion throughout the wound by sticky lymph, and no sign of tenderness anywhere, such as indicates retained fluid or other source of avoidable inflammation. One hears of the ends of bones being cut off in compound fracture and dislocation to permit of replacement. This, surely, must be seldom, if ever, required by reason or mechanical judgment, for a bone may naturally be expected once again to lie where it has previously lain. But if the opening in the tissues do not permit of easy replacement, that surely can be enlarged until the depths of the wound are freely accessible. In compound fracture or dislocation the importance of having a wide opening, in the event of much laceration, comes next to that of securing disinfection of the wound, and contributes probably as much to its subsequent protection from irritation. Complete relaxation of the textures throughout is more important than rapid union of the skin, and in such wounds is often quite incompatible with the latter. In thus appearing to ignore the attempt to procure primary union that result is in reality attained, but not in the tissues where its attainment is more commonly sought. By avoiding primary union of the skin, where it is not always important, it is readily acquired in deeper parts, where it is really of value. This has long been inculcated by Professor Lister, and its importance as a truth cannot be over-estimated. The primary union of the deeper soft parts thus took place in freely lacerated tissues, that in former times were supposed to be generally incapable of such adhesion; and this is now familiar under circumstances of successful disinfection, relaxation, and mechanical rest. The wound in the skin was shaped as cleanly as if cut with a knife, although effected by laceration. This circumstance, familiar enough in surgical practice, has an important bearing upon medico-legal questions, as showing how utterly impossible it is to always predict, from the mere shape of a wound's edges, by what means the division has been effected. A lacerated wound has often clean-cut edges, while an incised wound may be jagged and irregular. (3) The dislocation was in some attitudes irreducible. No splint, not even the hands of an attendant, could have kept these bones together in any attitude of extension up to or beyond a right angle. By their own weight they thus fell apart. But flexed acutely the notch of the ulna was locked on the lower end of the humerus, suspended by the triceps behind and the wrist in front. The arm hung comfortably on the chest, and was further fixed to the side. The injured muscles being at ease, and subject to no call for the support of the bones, no pain was caused. It does not seem to be very generally known that acute flexion of the upper limb slung to the neck inside the clothing is a position of rest more effectual in the curative treatment of inflamed elbow than can be afforded by any splint. The writer can testify to the paramount importance of this mechanical item, which is as simple as it is effectual. No "passive movement" was here employed. The injured parts were kept almost absolutely at rest until they were healed, and devoid of all juiciness such as commonly attends the simplest reparative processes. It is no doubt true that many cases of injury, healing simply under aseptic conditions, and free from all added inflammation from any cause, may continue to run a simple unexaggerated course, even if slight passive movements be employed at each dressing. This proves nothing more than the tolerance by tissues, otherwise perfectly unirritated, of a slight degree of mechanical disturbance. There is fortunately a margin in the animal system within which the indulgence of extra exertions, and even of eccentric vagaries, may sometimes be harmlessly practised. But these are done at a risk which,

in certain cases, proves the ruin of a joint, a limb, or a life. Those who are habitually addicted to the practice of passive motion seem so fully persuaded of its necessary benefit in cases where it does no harm, that they appear to be incapable of noticing the instances where delayed healing, stiffness, and other complications, directly result from this practice, or from the too early resumption of voluntary motion on the part of the patient.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

The Treatment of Acute Peritonitis by Abdominal Section.

AN ordinary meeting of this Society was held on the 10th inst., Dr. George Johnson, F.R.S., President, in the chair. The discussion on Mr. Treves' able paper lasted the whole of the evening.

Mr. FREDERICK TREVES read a paper on the Treatment of Acute Peritonitis by Abdominal Section. The extreme fatality of acute diffused peritonitis, especially of that form due to perforation, and the acknowledged futility of the modes of treatment that are at present employed, give some support to the proposal that acute peritoneal inflammations should be treated by the same methods that are successfully applied to other acute inflammations—viz., by free incision and drainage. This common and general surgical procedure has been already applied for the relief of inflammations of certain of the serous membranes. It was at first adopted in connexion with the smaller serous cavities as those of the joints. It has been gradually and with increasing freedom applied in the treatment of inflammatory conditions involving the pleura. It has finally become a recognised means of treatment in certain forms of localised and chronic peritonitis, especially when purulent collections have formed. The author would urge the adoption of this principle in treatment in connexion with acute and diffused forms of peritonitis. The following case was narrated:—A female, aged twenty-one, was admitted into the London Hospital on January 21st, suffering from chronic pelvic peritonitis following severe gonorrhœa. On February 25th, three months after the commencement of the chronic peritonitis, she suddenly developed the symptoms of acute diffused peritoneal inflammation. The sequel showed that a large chronic purulent collection, containing very offensive matter, had formed near the left pelvic brim. The walls of the abscess were formed partly by the pelvic peritoneum and partly by many coils of small intestine that had become matted together. The acute symptoms were due to the bursting of this abscess and the extravasation of its contents into the general peritoneal cavity. On Feb. 26th the abdomen was opened under antiseptic precautions, the patient being at the time apparently in a very critical condition. The general surface of the peritoneum showed the ordinary appearance of acute peritonitis. The intestines, where in contact, were lightly glued together. A quantity of semi-opaque fluid, mixed with flakes of lymph and pus, escaped. The whole peritoneal cavity was washed out with many quarts of water and a drain introduced. The patient made a good recovery, and was allowed in the garden on the fortieth day. The author alludes to several cases in which operations involving laparotomy have been performed with success during the progress of acute peritonitis, the cases having been in most instances the subjects of error in diagnosis. Allusion is also made to the recent experiments on dogs by Dr. Parkes, of Chicago, as to the treatment of penetrating gunshot wounds of the abdomen, with perforation. The author ventures to suggest the use of abdominal section in the treatment of certain cases of acute general peritonitis, such as that following injury, gunshot wound, the bursting of an abscess, and specified forms of perforation.

Mr. HOWARD MARSH read a paper on Acute Circumscribed Suppuration of the Peritoneum, treated by Abdominal Section, with recovery. The patient was a medical student, aged nineteen, who was under the care of Dr. Andrew first on Dec. 17th, 1883. He had suffered from constipation. When first seen the abdomen was distended and tender; there was no external hernia. To the left of the umbilical region, a swelling, eight inches square, was to be felt, which was dull to percussion and painful, and there was a sensation of fluctuation in this swelling, and the skin over it was œdematous. An exploratory operation was decided upon. Vomiting had reduced the patient to the last degree. The patient was placed under chloroform, and an incision was made outside the linea semilunaris, when two or three pints of fetid pus escaped. The distended coils of small intestine could be felt through the wound, which was washed out with a 1 in 60 solution of carbolic acid, by means of a soft indiarubber catheter. A drainage-tube, eight inches long, the size of the little finger, was introduced, and carbolic dressings were used and retained in place by lightly applied bandages. At the end of four hours the patient rallied somewhat, and the pulse was 96, the temperature being normal. Much vomiting of merely clear bilious liquid was a source of trouble. On Dec. 20th the pulse was 96, and the temperature normal. The patient slept fairly well. The vomiting occasionally recurred. Morphia was used to give sleep and relieve pain. A profuse discharge continued to escape, but the drainage-tube was shortened by an inch and a half. The patient was fed by nutritive enemata, and had taken nothing but a little iced water by the mouth. At this time the swelling still extended towards the right iliac fossa. On Dec. 21st the temperature was 99°, but the area of dulness was diminished. The patient passed many light-yellow liquid motions. He had now begun to take milk and beef-tea by the mouth. On Dec. 26th the patient was much better, and the fæces were partly formed. He ate a minced chop on Jan. 4th; he got up on Jan. 12th. On Feb. 20th the notes said that, with the exception of an attack of vomiting, the patient had progressed favourably. On March 7th the wound was healed, but the bowels never acted without enemata. Dr. Andrew and Mr. Marsh had come to no definite conclusion regarding the nature of the disease, but it was thought that an abscess in the mesentery around old tubercular glands might have burst. The disease was so very extensive that it could hardly be regarded as an ordinary circumscribed peritonitis. Further exploration was not made for fear of rupturing softened intestinal coils, and thorough exploration would have necessitated considerable enlargement of the wound. The patient was youthful, but probably an older patient would have died from exhaustion. He thought that in cases where there was any definite collection of pus in the peritoneum the abscess should be opened and freely drained. He did not think that the operation would be attended with any large amount of success in cases of suppuration of the whole peritoneum, because of the extensive surface involved and of the difficulty of drainage afterwards. Furthermore, obstruction of the bowels dependent on the formation of extensive adhesions might be set up. In one case of the kind there was some fear that the obstruction was dependent on impaired peristaltic action, the result of the adhesions formed.

The PRESIDENT said that it was plain that the surgical procedure had saved the life of each patient.

Mr. THOMAS BRYANT thanked Mr. Treves for his valuable paper. The value of the paper was enhanced in that it advocated the application of well-recognised surgical principles to the treatment of abdominal abscesses. He thought that cases from other quarters to prove the correctness of his views might have been brought forward by Mr. Treves. Such, for example, as cases of abscesses about the cæcum, which, as Mr. Treves showed in his admirable demonstration at the Royal College of Surgeons, were really abscesses of the peritoneum, for there was no portion of the cæcum that was not surrounded by peritoneum. So that in all cases of cæcitis and in cases of localised suppuration around the cæcum the surgeon has had to deal with the peritoneal cavity. He had long felt that the practice advocated by Mr. Treves was one which had not been sufficiently followed. He had, however, for ten years past performed surgical operations on cases of localised suppuration in the peritoneum about the cæcum and pelvis. The cause of the peritonitis must determine whether the surgeon should operate or not. We did not recognise acute suppurative peritonitis as a disease by itself; peritonitis was the effect of some antecedent condition. The ultimate result of the treatment would be dependent on the cause of the peritonitis. He referred to a paper by Mr. Thomas Smith, by whom this subject was brought before the profession, it was published in the ninth volume of the St. Bartholomew's Hospital Reports.

Mr. KNOWSLEY THORNTON said that there was a form of peritonitis which appeared to be due to the mere presence

of the tumour, and not to any perforation; whether strain or chill aided in the causation he could not say; but it was to this form of acute dry peritonitis that he would refer. On opening the peritoneum during life it was absolutely dry, velvety, and red. There were no neighbouring adhesions. The first case in which he had performed the operation the patient died, with a high temperature and complete suppression of the urine. It would perhaps have been better to have waited till the acuteness of the inflammation had passed away. A second case was referred to, in which, after some time, the patient was greatly collapsed. The peritoneum was opened, and the same kind of dry peritonitis was discovered. The patient recovered after a very severe illness. He asked whether the condition of the intestines in Mr. Treves's case was one of intense vascular injection. In cases of perforation, the proper course was to operate at once. Drainage was a most important point. He did not think that the results of operation for gunshot wounds would be so good as in cases of perforation. With regard to the method of dealing with these cases, it seemed to him, unless the surgeon could be certain of obtaining absolute asepsis, antiseptic irrigation had better not be used. Where asepsis was impossible, he should use large quantities of boiled water, with free drainage, in addition to the other means of dealing with the injured parts.

Dr. DOUGLAS POWELL said that physicians were familiar with cases of peritonitis which were idiopathic and which were not suppurative. So that he thought that the title of Mr. Treves's paper should have been "The Treatment of Suppurative Peritonitis." Cases of peritonitis might be looked upon as analogous to cases of pleurisy where we had to distinguish between suppurative and non-suppurative forms. He thought that the treatment of all cases of suppurative peritonitis should be conducted on strict antiseptic principles, and did not agree with the remarks of Mr. K. Thornton.

Mr. BARWELL narrated a case of Perityphlitis in a gentleman, in which an incision was made and eight ounces of pus let out; a counter-opening enabled twenty-four ounces of fetid pus to be discharged from the peritoneum. The wound was irrigated with large quantities of weak carbolic solution. Death took place eighteen months after the operation from phthisis pulmonalis. He was in complete accord with the views of Mr. Treves.

Dr. GOODHART said he had been led to the opinion that surgery was nothing if not aggressive. He did not, however, consider that Mr. Treves had gone far enough; some cases of acute peritonitis not of the suppurative variety might be treated by abdominal section, though he confessed that Mr. Thornton's facts did not fit with his (Dr. Goodhart's) theories. Death took place in some cases of acute peritonitis from collapse, due to septic causes; the mode of death in these cases resembled that in dogs dying from the injection of artificial sepsin, and was of an almost sudden kind, though due to blood-poisoning. A case of obstruction of the bowels, for which Littré's operation was performed after the method first adopted by Mr. Howse, was mentioned; in this some turbid fluid escaped during the first stage of the operation, and no more symptoms of obstruction remained, so that the second stage of the operation was never done. A growth in the bowel was found when death took place some months later, but the symptoms were due to the peritonitic condition, which the operation had relieved. There were a few cases of simple ascites, in which surgical interference might be sought by the physician; these cases were tapped time after time, and were sometimes due to cirrhosis or perihepatitis, and had recently been recorded as cases of "cirrhosis cured by tapping." Here, no doubt, there was agglutination of the visceral and parietal laminæ of the peritoneum, and the collateral circulation set up in the adherent membranes led to the cure of the ascites.

Mr. MEREDITH said that a 1 in 40 solution of carbolic acid was not sufficient to destroy any existing septic matter in cases of septic suppuration, and so he concurred in the remarks of Mr. Thornton.

Dr. DOUGLAS POWELL said that he believed that a weak solution of corrosive sublimate might be used, and would be sufficient to destroy septic matter. A hypodermic syringe for the purpose of ascertaining the state of any fluid collection in the peritoneum would prove most useful in practice.

Dr. GEORGE JOHNSON said that he for one should not hesitate to call in the aid of the surgeon in such cases. He asked whether in a case of simple ulcer of the stomach the surgeon would be prepared to interfere. Such cases were almost invariably fatal, though he knew of one case of recovery in which the patient was fed for twenty-seven days per rectum.

Mr. TREVES, in reply, said that with regard to Mr. Marsh's objections "on principle," he did not think they were borne out by Mr. Marsh's own successful case. From a common-sense surgical point of view, mere magnitude of the abscess ought not to deter the surgeon. The experience of ovariotomists showed that it was possible to clean the peritoneum very perfectly. Where the operation was done with a view of saving life, the occurrence of adhesions afterwards should hardly be weighed in the matter. It was probably a question of physics rather than of actual surgery whether opening of the abdomen would not relieve congestion of any vessel contained therein. As to the stage of the peritonitis, there would probably be some difficulty in defining the term "acute;" but cases in which he had urged operation would not admit of delay. In the last number of the *New York Medical Journal* Dr. Bull had recorded a case of pistol wound of the abdomen with four or five perforations of the bowels. The peritoneum was washed out, but the bowels were not resected, yet the patient made a perfect recovery. With regard to Dr. Powell's suggestion of corrosive sublimate, it should be borne in mind that an albuminate of mercury would be formed, and the antiseptic effect of the sublimate would be minimised thereby. Speaking generally, he thought the surgeon was called in as a last resort by the physician, and he much regretted that such should be the case.

Mr. HOWARD MARSH, in reply, said that he had not intended to convey the meaning put upon his remarks by Mr. Treves. In large abscesses of the peritoneum it would be difficult to keep the peritoneum thoroughly drained afterwards. That adhesions resulting from the operation could cause fatal obstruction of the bowels was proved by a case which had been under his observation.

MEDICAL SOCIETY OF LONDON.

Remarks from the President.—Ipecacuanha in Dysentery.—Infective Endocarditis (Mycosis Endocardii).

AN ordinary meeting of this Society was held on Monday last, Dr. W. Miller Ord, President, in the chair.

The PRESIDENT, on taking the chair for the first time, congratulated the Society on its very great success. He felt the honour to be the greater in that he had been made president at a time of great prosperity in the Society. He proposed to devote himself, in the fullest sense of the term, to the duties of the Society. He referred to Mr. Durham's most successful year of office, and spoke of his earnest love of science, of his devotion to his profession, to which all could bear ready testimony, as well as to his qualities as a man, to his gentleness, truth, and kindness. He considered that the presence of general practitioners of high standing added largely to the value of the proceedings of the Society. He dilated on the advantages of general practice; the practitioner was able to study the man in relation to the malady, and did not regard his patient as a case of this or that disease. There were many problems to which the general practitioner could contribute more largely and more usefully than the consultant or specialist. He was brought into closer relationship with his patients, knew their life history by personal observation, and was therefore better able to estimate the personal reaction of the patient.

Dr. MACPHERSON read a paper on the history of the Use of Ipecacuanha in Dysentery. The drug was introduced into European practice during the last decade of the seventeenth century, as a remedy for the bloody flux; in this malady it acted like a charm. Helvetius considered it as specific in dysentery, as mercury in syphilis, or cinchona in malaria. After being highly prized for about half a century it fell somewhat into disfavour in England and France; but it was habitually used in small doses until the end of the last century. Akenside used very small doses—one grain every six hours; but other physicians recommended either one large dose or several smaller ones (five grains), repeated every hour until vomiting was produced. Subsequently very large doses, even frequently repeated, were highly favoured in the tropics, but it was almost entirely superseded by mercury as a remedy for dysentery, though never quite abandoned. In 1846 Dr. Parkes said that ipecacuanha was of quite secondary importance, but recommended small

doses. Sir Ranald Martin used doses of ten grains at least. Since 1858 the use of ipecacuanha has been the main feature in the treatment of dysentery, and though something must be put down to improved hygiene and the abandonment of bleeding, still the diminution of the mortality among the troops pointed to the probability that the drug was really of use in saving life. The French also now use the drug in large doses in the tropics and in America. Bartholow and others had found it useful. From a consideration of the general experience, he was inclined to say that the dose should not exceed thirty grains nor fall below five. He referred to the temporary popularity of mercury during the first half of the present century, and mentioned that even scruple doses of calomel were at one time commonly given, and were supposed to have a specific action on the mucous membrane in dysentery. Ipecacuanha had now entirely replaced it.—The PRESIDENT thanked Dr. Macpherson for his learned and valuable retrospect.—Sir JOSEPH FAYRER thought Dr. Macpherson's account a most valuable one, but he insisted that to Mr. Docker we owe the practical introduction of this remedy into medical practice in the British army. No doubt dysentery, when taken in its early stage, was most amenable to treatment, and ipecacuanha in twenty-grain doses at intervals of six hours was the best method of administration.—Mr. STOKER referred to his experience in the Russo-Turkish war.—Dr. CULLIMORE said that dysentery varied greatly in different constitutions. Ipecacuanha was of more value in dysentery of women than of men, probably because diseases of the liver were less frequent in women.—Sir JOSEPH FAYRER gave the following statistics. The British army in India in 1882 numbered 57,269 men, and of these there were 1629 cases of acute dysentery, and 33 died, or a mortality of ·51 per 1000. The Native army was 114,894 strong; 5223 cases of dysentery occurred, and 70 were fatal, or ·61 per 1000. The gaol population was not composed of the selected men that composed the armies; of these there were 94,063, and the number of cases of dysentery was 8866, of which 798 died. Of this population there were also 9863 cases of diarrhœa, of which 683 died; so that, taking these diseases together, there was a mortality of 15·21 per 1000. All the cases were treated by ipecacuanha, and it was in simple uncomplicated cases of dysentery that this drug was useful. In cases of chronic diarrhœa and chronic dysentery rest in bed and diet were the most important elements; but even then, when exacerbations of an acute kind supervened, ipecacuanha was just as valuable as in acute dysentery.—Dr. MAIR referred to the variability of ipecacuanha as a drug; some specimens were untrustworthy, and these sometimes smelt musty.—Dr. THOROWGOOD spoke of the value of ipecacuanha in cases of chronic diarrhœa.—Dr. MACPHERSON briefly replied.

Dr. SIDNEY COUPLAND read a paper on a case of Malignant Endocarditis (Mycosis Endocardii). The organs were exhibited, and also drawings of vegetations from the mitral valve showing the site of the micro-organisms. There was a "button-hole" mitral valve, and masses of vegetations, which had caused a good deal of ulceration, were present on the auricular surface of the sclerosed valve. The spleen weighed eighteen ounces and a half, and was very large; it was in great part necrosed with large wedge-shaped areas of infarctions in various stages of degeneration. The kidneys were in a state of recent nephritis and contained infarctions. The lungs were the seat of lobular pneumonia, collapse, and œdema. The left centrum ovale was lacerated by a large recent blood-clot. The patient was an anæmic, strumous girl, aged fifteen, and was first seen on Oct. 19th, 1880. She had had acute rheumatism six weeks before. The mother had recently suffered from rheumatic fever. The physical signs indicated some hypertrophy, and the murmur was presystolic and accompanied by a thrill. The rheumatic signs in the joints, which were present on admission, subsided in a few days. A systolic bruit appeared at the base of the heart. Three years later, on Nov. 19th, 1883, the patient was admitted again with præcordial pain and palpitation; headache and attacks of syncope had frequently occurred; swelling of the feet had lately set in. There was much anæmia. The cardiac impulse was diffused and wavy; the impulse at the apex was thrilling and thrusting. There was a loud blowing murmur at the apex beat, which was conducted into the axilla and to the back. There was no albuminuria. The temperature was about 100°. On Nov. 25th there was a single spontaneous attack of vomiting. The anæmia increased. The temperature at times rose to 103°. The patient was kept under observation, and readmitted on Nov 25th 1884. There was continued but low and irregular fever. The spleen was enlarged, and pain was felt in that region. On Jan. 5th, 1885, there was a painful swelling, with discolouration of the lobe of the left ear, followed by a similar condition of the right ear. On the 8th there was a symmetrical purpuric rash on the cheeks; a trace of albumen in the urine was found on and after the 9th; on the 12th, fresh purpuric spots were seen in the cheeks and in the left pinna; on the 17th the rash had faded, when a recrudescence set in, and the skin had a sclerodermatous feel. Dr. Liveing thought it allied to peliosis rheumatica. On the 28th the patches on the cheek were fading. The heart's action was tumultuous. On Feb. 6th a few fresh patches appeared on the skin. The cardiac area of dulness was increased; the presystolic thrill was well marked. The final scene was attended with unconsciousness and right hemiplegia of sudden onset. Dr. Coupland commented on the case, and said that it was not one of those which Dr. Osler classed as of the septicæmic variety, but was what he would call of the "cardiac" kind. As to the reason why cases of chronic valvulitis should be so prone to take on this form of lesion, he thought that possibly debility and anæmia favoured its occurrence. The present case and one he had reported in THE LANCET last year told in favour of this view.—Dr. T. H. GREEN said that Dr. Coupland was the first to point out that this disease supervened on old cardiac disease. In his opinion a case of intermittent or remittent pyrexia occurring in the course of valvular disease of the heart, and in the absence of other obvious causes, would most probably prove one of infective endocarditis. He referred to the case of a young lady which lasted for ten months, and was probably one of this disease.—Dr. K. FOWLER discussed the question whether infective endocarditis was necessarily a fatal disease. The specimens shown by Dr. Coupland seemed to show that some of the infarctions were of old date. He said that Mr. Watson Cheyne had found micro-organisms in cases of purpura hæmorrhagica.—Dr. COUPLAND, in reply, thought it not at all improbable that cases of infective endocarditis might recover. The interest of cases of this disease was manifold, and the extreme diversity of the clinical picture was most remarkable; cases might prove fatal in a few days, or they might be prolonged for months.

ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Pathological Section was held on Jan. 16th.

The President of the College of Surgeons (Dr. BENNETT) exhibited some specimens of Congenital Dislocation of the Hip-joint. The first was taken from a child aged six years, who died last spring in Sir Patrick Dun's Hospital. At the time of her admission he had little hesitation in diagnosing double congenital dislocation of the hip. The child was then perfectly healthy in other respects. The midwife who attended at the child's birth stated that the presentation was normal and the labour perfectly healthy. In the first two years the deformity was not noticeable; but it was observed that she was slow in walking, and that she began to waddle. The first question was whether the increasing lameness could be arrested? She could stand with ease and steadiness, and could run with facility, but could walk only indifferently. Being attacked with scarlatina, of which there was an epidemic in the ward, signs of tubercular meningitis appeared, and after a couple of weeks she died. He was only able to exhibit the pelvis and the upper extremity of the femora. The gluteus maximus on both sides was reduced in part to a membrane, and the muscular fibre was almost entirely replaced by fat and tough fibrous tssue. The casts exhibited showed how complete was the separation of the knees, and also that inversion was wholly absent. No tumour was found beneath the gluteus maximus by the head of the femur, because the latter was directed forwards. The capsular ligaments were greatly thickened, and were more like fibro-cartilages than ordinary ligaments. There was no perforation of the ligaments on either side, but they were equally thick, dense, and hypertrophied. The attachments of the ligaments to the capsules were normal; but the acetabulum was dragged into an abnormal position. The true acetabulum was filled with fat. The seat of the new articulation was above and behind, but there was no bone exposed. No socket was formed in the bone, its formation being prevented by the

interposition of the capsule. On the right side the ligamentum teres was found to be represented by a curious leaf-like structure continuous with the cartilage, and having no connexion with the acetabular cavity. On the opposite side destruction of the ligamentum teres had proceeded to a lesser extent. These facts explained many recorded cases in which the ligamentum teres was said to be altogether absent. In each case of the kind the extent to which the ligamentum teres underwent absorption was simply a question of time. Had the girl lived a few years longer the ligament would have appeared to be entirely absent, and the dislocation attributed probably to its absence. In the majority of cases it was present, but undergoing absorption. The other specimen was one which he had himself dissected, and it repeated all the phenomena of that of the case from Sir Patrick Dun's Hospital.

Dr. KILGARIFF exhibited a large Cervical Tumour removed by him from a young woman aged twenty-five. A similar growth had been removed from the same place six years before. It implicated the lower part of the ear, the face, and the ramus of the jaw, the side of the neck overlapping the clavicle, and lying on the sheath of the carotid and deeply embedded in the parotid region. It became ulcerated six months before operation, and she became much reduced by the hæmorrhage from the ulcer. Photographs were shown of the patient before and after the operation, which proved very successful. Mr. Coppinger having examined the growth, reported that it was encapsuled, and that the fresh section showed large translucent areas. Microscopically the sections presented the characters of myxomatous tissue. The outer parts were chiefly made up of lymphoid tissue. He considered it a lympho-sarcoma.

Dr. J. W. MOORE exhibited some large Gall-stones. In 1882 he had presented to the Pathological Society a series of gall-stones which had been passed by an elderly woman after terrible suffering. A peculiar feature of the case was that there was very little icterus, explained probably by the remarkable faceting of the calculi. The calculi had been in his possession since last summer. The woman recovered perfectly.

Dr. BARTON exhibited a specimen of Bowel Obstruction. The patient, an engine fitter, aged thirty-four, had suffered occasionally during six months from derangement of the digestive organs. He had no history of dyspeptic symptoms, but complained last summer of colicky pains after food, a peculiar pain across the abdomen with a sort of gurgling. These symptoms occurred at irregular periods, and in the interval he had good health. On Christmas Eve he had a severe attack of abdominal pain and obstinate constipation. For ten days he suffered from these symptoms, with partial obstruction, swollen abdomen, and peristalsis of the intestines, perceptible through the abdominal walls. He had occasional action of the bowels, produced by enemata, in which the excreta were of a soft character. When admitted into the Adelaide Hospital on the 5th inst., his abdomen was swollen, the chief point of pain being on the right side over the cæcum. Pressure on the rest of the abdomen did not cause much pain. He appeared like a person suffering from strangulated hernia. He had a long drawn face, and vomited matter of a distinctly fæcal character. It was concluded he had intussusception of the ileum to the large intestine at the ileo-cæcal valve. The swelling had increased to such an extent as to account for the total obstruction which existed for three days. He was put under opiate treatment. Having gone prepared to operate, Dr. Barton found the patient had free action of the bowels, which was followed by a second after his arrival, the fæcal matter being soft and fluid, evidently from the small intestine. The abdominal swelling and pain had diminished and the vomiting ceased, although he could not retain food. For the next five days the treatment was on the supposition of inflammatory obstruction, not an intussusception. He gained ground till three days ago, when the pain and vomiting returned, and, treatment availing nothing, it was determined to operate. Opening the abdomen as a tentative measure, to ascertain the pathological conditions, Dr. Barton made an incision from the umbilicus downwards, and found that the parts about the cæcal valves were not obstructed. The ileum was thickened and the cæcum enormously distended, but there was no intussusception. At the transverse colon he discovered a hard mass with a hard band of lymph around it, about as thick as the little finger, and he divided it. Immediate relief followed. This was only part of the diseased mass, and he excised a portion of the transverse colon and sewed the cut end of the ascending colon to the upper end of the wound, the rest of which he fastened up, so that the man, who was still alive, had got a false anus. The operation occupied two hours. Whether the man would survive or not was doubtful, the shock having been very great. The wall of the intestine was occupied by a mass which nearly filled the cavity, leaving passage barely for a quill pen. The fizzing noise which attended his temporary relief from pain and obstruction months back was evidently caused by the passing of the liquid fæces through the opening. The obstruction was of the inflammatory kind, though the mass was exceedingly hard. It grated under the knife, and seemed of a fibrous character. The condition of the ileo-cæcal valve was that of inflammatory thickening.—A discussion followed, in which the President, Dr. Warren, and Dr. Doyle took part; and Dr. Barton having replied, the section adjourned.

CAMBRIDGE MEDICAL SOCIETY.

AT the meeting on Feb. 6th, Dr. Bradbury in the chair, Dr. BOSWELL (Saffron Walden) related a case of Supposed Cerebellar Embolism. Early in May, 1884, he was called to see a patient, aged fifty, suffering from rheumatism, which shortly after assumed an acute form. The salicylic treatment was adopted and the disease checked, though not before an impurity of the heart's first sound had become noticeable over the mitral and aortic areas. On June 7th she was able to sit up, and felt very well. Next day, while quietly resting in bed, she suddenly pressed her hands over her head and with a cry of terror fell over. She was conscious, but unable to articulate; the face was greatly flushed and somewhat swollen, the conjunctivæ were congested, the eyelids dropped, and the pupils much contracted and turned upwards. Nystagmus was observable when the eyes descended. There were, moreover, very remarkable writhing movements, the patient all the while lying close to the bed and not raising herself from it in the least. There was no indication of any form of paralysis, either motor or sensory. The reflexes were exaggerated. Next day she was able to communicate her sensations. She was suffering from an overwhelming sense of vertigo, objects appearing to be whirling round her, not laterally, but from behind forwards on a vertical plane. The left pupil remained contracted for three weeks. She complained much of extreme photophobia, and consequently an ophthalmoscopic examination was not possible. Tinnitus aurium was also a marked feature. There was no evidence of inflammatory mischief, and the temperature was normal. The bloodvessels were healthy. In this condition of extreme prostration, with total inability to raise her head from the pillow, she remained for several months. Latterly she has improved somewhat, and has been able to sit up a short while each day, to occupy her time a little with reading and needlework, and to walk round her bed once or twice daily. But she is still unable to occupy any but a horizontal position except for a very short time, and the vertigo and other sensations are very easily produced, particularly by any change of character in the visual impressions—such, for instance, as viewing her room from a different standpoint, or occupying a couch of lower level than the bed she habitually occupies. The probable pathology of the case was discussed, and the view adopted of an embolus being impacted in one of the cerebral arteries, or in a branch of the posterior cerebral artery on the left side. The experiments of Flourens were referred to as indicating the results of injury to various portions of the cerebellum, and also as affording grounds for a favourable prognosis.

Mr. W. R. POLLOCK showed a specimen of Fracture of Pelvis with Wound of Artery. The patient was fifty-six years old, and very stout; he was admitted into the hospital on April 9th, at 10.30 P.M. He had been knocked down by the buffer of a passing engine, but not run over; the blow was on the buttock. He was suffering great pain and was quite unable to walk, but his pulse was good and there was no sign of shock. He was put to bed without further examination, and he died about 5.30 A.M. on the following morning. The necropsy revealed a fracture of the pelvis and a spicule of bone penetrating the left internal iliac artery, causing internal hæmorrhage; there was also fracture of two or three of the upper ribs on the left side. Mr. Pollock remarked on the absence of shock or collapse, and the long time the patient lived after the wound of a large artery. The hæmorrhage was very gradual, although

the wound of the vessel was considerable. He referred to three cases recorded in THE LANCET by Mr. Clement Lucas of fractured pelvis with wound of either the iliac vein or artery; one patient living for six hours with a wound of the external iliac artery.

Mr. ROGERS (Fulbourn) showed a specimen of Sarcoma of Kidney removed from a lunatic in the asylum. Hæmaturia was first noticed in April, 1883, lasting for ten days and accompanied by pain. The patient recovered, but in December continuous hæmaturia persisted, until death occurred in November, 1884. A growth was found in the kidney, occupying a large portion of its pelvis and extending into the medulla and cortex; on section it showed several hæmorrhages and cystic degeneration. Microscopically it proved to be a sarcoma, with some indication of an alveolar arrangement. There were some calculi in the lower part of the pelvis of the kidney, the association of which with malignant disease was noticed. There were no deposits in the other organs.

MIDLAND MEDICAL SOCIETY.

AN ordinary meeting of this Society was held on Feb. 18th, the President, Mr. T. H. Bartleet, F.R.C.S., in the chair.

Mr. Ross JORDAN read a paper on the Social Aspect of Imbecility and Insanity. He pointed out the great importance of the subject and the desirability of the medical profession being prepared to advise their patients in such cases. After speaking of the early symptoms of insanity and their importance, it was urged that if home treatment did not speedily cure or improve the patient he should in all cases be sent to an asylum. He deprecated the practice of keeping insane patients at home. He pointed out that epileptics often have long intervals of sanity under control, but that the attacks are much more frequent and dangerous when at home. Moral insanity and some special manias in his opinion are not sufficiently recognised by law; it should be made legal to detain and treat many of these cases. The difficulty and danger of diagnosing and certifying private patients in the present state of the law were enforced, and the right of appeal to experts appointed by the Commissioners in Lunacy was suggested.

Mr. JORDAN LLOYD showed the parts removed from a Strangulated Congenital Hernia with Testis retained in the Inguinal Canal. The patient had been ruptured since childhood. Two days before admission the rupture came down with symptoms of strangulation. Operation was performed on the third day, the sac and atrophied testis being excised. He left the hospital on the twenty-third day without an impulse and is wearing no truss. Mr. Lloyd also exhibited eight other hernial sacs recently removed by himself. He also showed a specimen of Infiltrating Lympho-sarcoma removed from the Posterior Triangle of the Neck. The growth seemed to begin in the deep cervical fascia, and at the time of the operation had infiltrated the platysma and sterno-mastoid, the clavicular part of which was removed. The patient left the hospital on the twenty-sixth day with the wound soundly healed.

Mr. BENNETT MAY exhibited a specimen, taken from a man aged fifty-four, of Cancer of the Cæcum of the ordinary cylindroma form, which, by compression of the duodenum at its second bend, had caused death by protracted starvation. The intestinal symptoms being slight, and no tumour being perceptible for some time, the case was difficult of diagnosis in its earlier stages, and was further complicated by the formation of a large abdominal abscess due to ulceration.

Mr. EALES showed a man in whom the Iris was completely absent in each Eye. Both lenses were opaque, after the zonular type, but with many striæ in the clearer outer zone, and in each eye the lens was abnormally placed, being nearer the upper than the lower corneo-scleral junction. The removal of the lens in one eye showed the vitreous to be quite fluid. He also exhibited a girl, aged twelve years, suffering from Coloboma of the Iris and Choroid in the left Eye. The eye was hypermetropic, and the difference in refraction between the margin of the coloboma of the choroid and its deepest part was eight dioptrics.

SUPERANNUATION.—Mr. A. J. Verity, late medical officer for the Bridgend district, the workhouse, and the cottage homes, has received a superannuation allowance of £29 a year.

Reviews and Notices of Books.

Atlas of Female Pelvic Anatomy. By D. BERRY HART, M.D. W. and A. K. Johnstone, Edinburgh.

WE have on previous occasions noticed with pleasure the work done in the anatomy of the pelvis of the female by Dr. Berry Hart, and published from time to time. His researches into the anatomy of the pelvic floor and of the "genu-pectoral" position are of the greatest value. The imagination has been permitted to run riot by writers upon these two subjects, in evolving the functions of the one and the effects of the other, but the investigations of the author have brought them back within the realm of fact, a service of incalculable value to women. His researches into these subjects will contribute materially towards forming a basis for a true physiology and pathology of the parts in question. The Atlas of Female Pelvic Anatomy contains the illustrations of the subject already published by Dr. Hart, some new illustrations, and a large number selected from the works of others. The work consists of thirty-seven plates—almost every plate contains several figures,—and an appendix on the nervous mechanism of the bladder and the etiology of flexion. The plates are accompanied by descriptions, explanations, and practical remarks. They are grouped into six sections. The first seventeen plates are descriptive (as opposed to sectional) of the external genitals and the internal pelvic organs; the second section consists of three plates, chiefly of the fasciæ and muscles of the pelvis; the third illustrates in eight plates the sectional anatomy of the pelvis; the sections being made in various planes, transverse and perpendicular—in the pregnant and unimpregnated condition. Some of the figures in this section are diagrams, and for that reason alone their appearance is to be regretted, especially as they have been published by their designers to explain or illustrate theories the correctness of which is still questioned. The fourth section gives the anatomy of the pelvic floor and of the "genu-pectoral" position, which we have already stated Dr. Hart has rescued from cloudland. In the fifth section is given the state of the cervical canal during pregnancy and labour; the sixth and last is devoted to microscopic anatomy. We need add nothing to what we have said about the author's original work, which is reproduced in the Atlas. The task of selecting from the works of others has been on the whole well and judiciously done. Many of the subjects illustrated are still under discussion, and opinions the most opposite are held respecting them; consequently illustrations taken from specimens alone can be of any value; diagrams are useless, and do not add to our knowledge. With the exception of the diagrams above referred to, the selection for the first four sections has been done well. With regard to the fifth section, however, which illustrates the condition of the cervix during pregnancy and labour, the author has not been so fortunate. The subject is one which has by no means been settled since it was reopened by Bandl, by the publication of his memoir "Ueber das Verhalten des Uterus und Cervix in der Schwangenschaft und während der Geburt," in 1876, and it is not likely to be settled yet awhile. The illustrations in the Atlas fail to give a just and fair representation of the present state of the subject—do not give some of the most important figures of what has been seen, drawn, and published. The microscopical section is extremely deficient. With the exception of three illustrations on wood, the plates are of sections of the vagina and external parts, and show but little. Many of the illustrations were obtained by first photographing the specimens and then tracing them. This method has the advantage of accuracy, but it has disadvantages which render

photography in its present state unfit for anatomical illustrations. The plates thus obtained in many instances want definition and clearness, convey but a small part of what is seen in the specimens, and what the hand of an artist drawing from the original would clearly depict. This is the case to a greater degree in the plates of microscopic specimens; they show but little structure. This, however, does not detract from the excellence of Dr. Hart's own work, to whom and to the enterprising publishers great praise is due for such an excellent atlas of the anatomy of the pelvis of the female.

Intestinal Obstruction: its Varieties, with their Pathology, Diagnosis, and Treatment. By FREDERICK TREVES, F.R.C.S., Surgeon to and Lecturer on Anatomy at the London Hospital; Hunterian Professor of Anatomy at the Royal College of Surgeons of England. With 60 Illustrations. Cassell and Co. 1884.

THIS is one of Cassell's series of Clinical Manuals for Practitioners and Students of Medicine. Judging by the volumes published and the announcements of others shortly to appear, this series promises to be a very valuable one. The book before us is to a very large extent the essay which obtained the Jacksonian Prize in 1883, and it is easy to see that the adjudicators of that prize could have had no difficulty in finding the essay worthy of such a distinction. Throughout there is abundant evidence of patient labour, accurate observation, and sound reasoning; and we believe Mr. Treves's book will do much to advance our knowledge of a very difficult subject. Few cases come before the surgeon or physician which present greater difficulties in diagnosis and treatment than some forms of intestinal obstruction, and any work like the one before us, which renders real help in the solution of these problems, is sure to be largely read and cordially welcomed. The pathology and symptoms of the different varieties of intestinal obstruction are first of all very fully dealt with in separate chapters. No pains have been spared to render this part of the book, upon which all the rest depends, as complete as possible. The diagnosis of all forms of this disease is then separately considered in four chapters, and the treatment is discussed in the three concluding chapters. Each part is well done, and we can confidently recommend the book to our readers. We regret that the taste displayed in the selection of the colour of the binding and edging of the book is most unfortunate.

OUR LIBRARY TABLE.

Clinical Lectures on the Practice of Medicine. By the late ROBERT GRAVES, M.D., F.R.S., Professor of the Institutes of Medicine in the School of Physic in Ireland; to which is prefixed a criticism by Professor TROUSSEAU. Reprinted from the Second Edition by the late Dr. NELIGAN. London: The New Sydenham Society.—Dr. Graves's clinical lectures are among the modern classics of medicine without which any medical library is deficient. It is very good of the New Sydenham Society to save the library of younger medical men from excuse for such a defect. Of course much has been done in pathology and something in therapeutics since Graves's time. Such a reflection is not the least interesting one that arises in the mind on reading even the most famous of these lectures, as those on Fever and Paralysis, of which Trousseau thought so highly. But the fact in no way diminishes the value of the book, or lessens our estimate of the physician, who must ever remain a model, for the wide range of his knowledge, the fertility of his therapeutical resources, and the independence and soundness of his judgment. This work appears opportunely just now, were it only for the lectures on Cholera, a disease to which Graves gave so much study and attention, both as respects its mode of propagation and the best method of treatment.

The Year-book of Treatment for 1884. A Critical Review for Practitioners of Medicine and Surgery. Cassell and Co.—This is the first issue of a work which we hope will be continued yearly. It is the combined work of twenty-three contributors, who have not only abstracted the best contributions to the practice of medicine and surgery during the twelve months ending Sept. 30th, 1884, but have criticised them. The whole is compressed into 300 octavo pages, and the matter may be said to lie in a nutshell. The work appears to have been apportioned to the individual contributors with excellent judgment, and the result is a book of extreme value to all who in these busy times find it difficult to keep pace with the ever-advancing march of the science and art of medicine. Where the writing of a book is entrusted to several hands, its several parts must differ in their worth, and no doubt there is some inequality of merit in this Year-book. But we must confess that this is far less marked than might have been expected, and that anyone who will refer to the work will find it of real assistance and great value. The book is nicely got up, and issued at a price that puts it within the easy reach of all.

Practical Anatomy: A Manual of Dissections. By CHRISTOPHER HEATH, F.R.C.S., Holme Professor of Clinical Surgery in University College, London, and Surgeon to University College Hospital, &c. Sixth Edition. Revised by RICKMAN J. GODLEE, M.S. Lond., F.R.C.S., Demonstrator of Anatomy in University College, London, and Assistant Surgeon to University College Hospital. With 24 coloured plates and 274 engravings on wood. London: J. and A. Churchill. 1885.—This excellent manual of practical anatomy is so well known that little more is required at our hands than to call attention to the publication of this the sixth edition. Mr. Godlee has carefully revised the whole work, and has improved many of the directions for the dissections, but has in no way altered its general features. The large number of excellent illustrations make the work of great value to students, and should help them very much in the preparation and study of their dissections. The paragraphs under the heading of "Surgery" contain clear and practical descriptions of most of the operations of surgery, and remarks on the practical application of anatomy to medicine and surgery. The work altogether is a thoroughly trustworthy guide for the student, which fully merits the popularity former editions have attained.

St. Bartholomew's Hospital Reports. Edited by W. S. CHURCH, M.D., and JOHN LANGTON, F.R.C.S. Vol. XX. London: Smith, Elder, and Co. 1884.—The first article which attracts attention is a reprint of an original pamphlet which was first published in the reign of King Edward VI. It is entitled "The Orders and Ordinances for the better Government of the Hospitall of Bartholomew the Lesse," and has been supplied by Mr. Morrant Baker from amongst his "few treasures in the shape of old books." This reprint is well worth reading, both on account of its clear language and the interesting nature of its matter. As is customary with these reports, a large number of original articles have been contributed by the members of the staff of the hospital and school. Some of these call for special mention. Dr. Russell has an article on the Amount of Carbonic Acid in London Air. Dr. Samuel Gee has written a few papers on some miscellaneous cases which have been under his care; all these cases are of much interest and deal with subjects which are but little known. The chapter on Nervous Disorders affecting a whole family deals with a class of cases which have alliances with epilepsy, hysteria, insanity, and megrim, whilst being none of them. Dr. Ormerod has recorded some valuable notes on the later stages of hemiplegia. Dr. Dyce Duckworth has related a case of Acute Pemphigus in an Adult, fatal on the ninth day. Mr Berry writes on the treatment of Cancerous Stricture of the

Œsophagus by means of Railway Catheters and soft India-rubber Tubes. Mr. Willet gives a Summary of the Results of a Hundred Cases of Osteotomy. Dr. Norman Moore's article is on the history of the first treatise on Rickets. Dr. V. Harris contributes some observations on Anæmia. The following articles are also interesting:—Mr. T. W. Reid, Gastrostomy in Malignant Disease of the Œsophagus; Dr. West, Clinical Observations on Pilocapin; Mr. Buller, Intestinal Rupture; Mr. Hurry, Gangrene of Uterine Fibroids; Dr. Percy Kidd Fæcal Vomiting without Mechanical Obstruction of the Intestines; Mr. Walsham, the treatment of Lateral Curvature of the Spine; Dr. Brunton and Mr. Cash, Why do Medicines sometimes fail to act? Mr. Lewis Jones, Extensive Sarcoma of the Vertebræ, Sacrum, Ilium, and Sternum; Mr. T. Smith (a very important article), Traumatic Cephalhydrocele; Mr. Bowlby, Traumatic Fever not of Septic Origin; Dr. Church, Our Pharmacopœia and Apothecary's Shop. The reports of the Medical and Surgical Registrars are given at the end of the volume.

Transactions of the College of Physicians of Philadelphia. Vol. VII. Philadelphia: P. Blakiston, Son, and Co. 1884.—This volume contains many valuable articles, of which the following may be enumerated:—A Sketch of the Life of Dr. Thomas Stewardson; a Memory of Dr George Fox; a Memoir of Dr. J. Forsyth Meigs; a Memoir of Dr. Samuel Gross; Enteric Paraplegia, by Dr. R Bartholomew; Report of a Case of Abdominal Tumour somewhat resembling Pregnancy in a young married Woman, by Dr. J. H. Packard; Criticisms on the Specific Theory of Hydrophobia, by Dr. Dulles; a Case of Inflammation of the Cervical Portion of the Spinal Cord, probably the result of an injury, followed by Tetanic Symptoms, by Dr. Cheston Morris; Clinical Aspects of Cerebral Syphilis, by Dr. Horatio Wood; History of a Case of Perihepatic Abscess, by Dr. Bruen; on a New Method of Recording the Motions of the Soft Palate, by Dr. Harrison Allen—a most original paper; a Study of the Nutritive Branny Foods, by Dr. Randolph and Dr. Roussel; Cholecystotomy by Dr. Musser and Dr. Keen—an article containing an almost exhaustive account of all that has been done in connexion with this comparatively new operation.

Westminster Hospital Medical and Surgical Reports. This volume gives the statistics for 1883. The work has been well done by Dr. Hebbert and Mr. W. Arthur, the medical and surgical registrars respectively. Unlike many hospital reports, there are no original papers by members of the visiting staff. Dr. Hebbert has drawn up tables of fifty cases of enteric fever and of seventy-two cases of acute rheumatism, also one of fifty-nine cases of chorea, which have been treated in the hospital during the three years 1880-1883. Such tables are of much value.

Silverlock's Medical and Surgical Emergency Reference Book. London: H. Silverlock. 1885.—This little book of reference contains, in a handy and portable form, a large amount of information upon subjects so varied that the busy practitioner can hardly be expected to have their details ever present to his memory. As a means of saving time this *vade mecum* will be found most useful.

PROSECUTION UNDER THE DENTISTS ACT.—In the Cupar Sheriff Court on the 6th inst., a quondam confectioner in Dundee, and now residing in St. Andrews, was charged with a contravention of the Dentists Act, 1878. The libel set forth that the accused unlawfully used the title of "Dr.," and the titles of "D.D.S.," resident surgeon, "Dr.," and "D.S." The accused pleaded not guilty. His defence was that he had advertised that he was "not a registered dentist," and he contended that the titles used by him did not come under the jurisdiction of British law. After evidence, the charge was found proven, and the sheriff imposed a fine of £10, with the alternative of seven days' imprisonment.

CHOLERA IMPORTATIONS INTO LIVERPOOL PORT IN 1884.

THE annual report of the port of Liverpool gives an interesting account of the measures adopted there with a view of preventing the importation of cholera during the autumn of 1884. Ten vessels were reported by the Customs officers as having touched at Marseilles, and on their arrival they were severally dealt with under the provisions of the Order of the Local Government Board. In the case of seven of the vessels no sickness had occurred during the voyage, and the vessels and crews having been examined by the port medical officer of health, neither of them was detained, although in one instance some water which had been taken on board at Marseilles, but which had not been used, was taken out to sea by one of the Corporation steam hoppers. In one of these cases it was later on reported that one seaman who had gone to reside in Toxteth-park had suspicious symptoms of cholera, but the alarm proved to be unfounded. The three remaining vessels were the steamships *Niagara*, the *Tarapaca*, and the steamship *St. Dunstan*. The *Niagara* called at Marseilles on her way from Bombay; she discharged her cargo, took in water, and then left. Whilst at Marseilles one seaman suffered from diarrhœa, and after leaving, six more of the crew suffered. But they were alleged to have all recovered a week before arriving in the Mersey on August 1st, and since, on examination, no evidence of cholera was found present, there was no detention of either the crew or the ship. The *Tarapaca* was a sailing vessel, carrying a cargo from South America to Marseilles; she arrived at the latter place on June 6th, and lay within one hundred feet of the *St. Dunstan*. Not having any cargo for home, she took in a quantity of rubbish as ballast, engaged twelve men of various nationalities as a fresh crew, and left for Liverpool on July 12th at 7 A.M. In the afternoon one of the crew suffered from choleraic symptoms, and died on the 15th. On the 14th another man was attacked with similar symptoms, and on the 17th a third case took place. Three other men suffered from diarrhœa. On arrival in the Mersey on August 5th, the man who sickened on the 14th was still ill, and was removed to the port sanitary hospital. The ship was detained, the crew were left under supervision, the ballast and bilge water were mixed with carbolic acid before being got rid of, and after the latter was effected the vessel was declared free from infection. The *St. Dunstan* called at Marseilles on July 3rd on her way from Bombay to Liverpool. At Marseilles she discharged her cargo, pumped water from the dock into her tanks for ballast, took fresh water and provisions on board, and left on July 9th. The next day a seaman was attacked with typical symptoms of cholera, and died the following day. On the 14th another sickened and died on the 15th. The master and the crew nearly all suffered from diarrhœa. The dead men and their effects were all thrown overboard, and their cabins were thoroughly cleansed and disinfected. On arrival in the Mersey on the 18th the vessel was moved up to the Sloyne as an infected ship. Next day seven more of the crew were ill, two of them suffering from diarrhœa and great prostration. These two were removed to the hospital at New Ferry. On the 22nd these men were able to return to the ship; all the crew were then examined, and, being found recovered, a certificate to that effect was given. In the meantime the ship had been disinfected by the port authority, all the refuse from the ship, including ashes from the boiler fires and dirt, was taken thirty miles out to sea, carbolic acid was mixed with the tank and bilge water before these were pumped out, and after the crew had left the bedding and clothing were dealt with in the Corporation disinfecting stove. In this case, too, a report arose that one of the crew had sickened of cholera after landing, but the case turned out to be only one of colic, the consequence of careless dieting. The story, as stated by Dr. Stopford Taylor, gives an excellent description of the action which was taken by him, the assistant medical officer, and the inspectors, under the Cholera Order in force in this country.

THE LANCET.

LONDON: SATURDAY, MARCH 14, 1885.

THERE has, for some time past, been considerable tension in Germany between the advocates of the comma-bacillus theory of cholera-causation and those who hold aloof from the doctrine. This tension has, perhaps, been most obviously manifest in the discussions which the discovery of a bacterial organism in all the tissues of cholera-affected persons by Dr. EMMERICH of Munich have given rise to. The details of EMMERICH'S researches were placed before our readers in our issue of Dec. 27th, 1884; we now propose to supplement what was then recorded by a reference to some observations which have recently been made by Dr. HANS BUCHNER, one of NAEGELI'S most distinguished pupils, and which were called forth by some strongly adverse criticism of EMMERICH'S article (and in favour of KOCH) by Professor FLÜGGE of Göttingen, in one of the leading medical journals of Berlin.

It appears that BUCHNER, taking up the subject in favour of EMMERICH, was refused a hearing in the same journal—the bias in favour of the local microbe being, apparently, too strongly felt to admit of this. The *Klinische Wochenschrift*, however, recently published the reply, and, as the matter in question is one regarding which there is a general desire to obtain information from every available source, we give a brief epitome of BUCHNER'S remarks. He points out that KOCH himself had formerly insisted that in order to substantiate a bacterial origin to any disease it was necessary to show that the symptoms of the malady could be unequivocally accounted for by the number and distribution of the organisms alone—requirements which have hitherto not been fulfilled as regards the relation of the comma bacillus to cholera. It is a mistake to suppose that in this disease it is only the intestine that is affected, and that all the morbid phenomena may be accounted for simply by the transudation of fluid into the intestinal canal. The cases known as "cholera sicca" very decisively show that such is not the case, as, indeed, is acknowledged by KOCH, who assumes that a poisoning of the entire system takes place. This assumption, BUCHNER states, appears to be supported by the observations of histologists, which go to show that, even in the early stages of the disease, a finely granular infiltration of the cells of most tissues takes place; consequently, Dr. BUCHNER maintains, the organisms themselves should be distributed in the tissues generally, whereas comma bacilli are but seldom to be detected in the intestinal walls even, and not at all in any of the internal organs. To meet the opposition which such a condition invites, KOCH assumes that the bacilli generate a poison in the intestinal canal, which passes into the circulation, but it so happens that the intestinal mucous membrane is quite incapable of absorption during a choleraic attack, even allowing that these organisms are capable of evolving a virulent poison, which, however, is wholly undemonstrated.

It is further maintained that no corresponding relation exists between the numbers of the bacilli and the severity of the attack, seeing that it is often found that very severe cases of cholera have been observed in which but few could be detected, and, indeed, in which they seemed to be absent altogether. Equally inexplicable on this theory of a poison being generated in the intestinal canal is the extremely rapid reaction which is so frequently observed in the disease; it would be impossible for the bacilli to disappear so instantaneously from the intestinal canal as to account for this, whereas were the organisms distributed generally throughout the tissues of the body, it might reasonably be assumed that they could be rapidly destroyed by the reaction which takes place in the tissue cells.

Again, the result of experiments on animals, hitherto so strongly insisted upon as a necessary test of the virulence of any microbe, has in the case of the comma bacillus been thus far of a wholly negative character. Taking all these facts into consideration, BUCHNER very properly maintains that further observations *are* necessary, and that such researches as EMMERICH'S are not, as asserted by FLÜGGE, superfluous, and even injurious, to the progress of medical science. It is advanced that FLÜGGE was wrong in asserting that EMMERICH had found his bacteria in only a certain proportion of the choleraic organs examined; he had, on the contrary, succeeded in cultivating the same species of bacterium from all the tissues investigated, and, as there were some hundreds of gelatine-tubes experimented with, any mere accidental development of this organism is out of the question. Professor FLÜGGE further maintained that the mortality which followed the inoculation of guinea-pigs by EMMERICH was due to septicæmia, and not to cholera—a suggestion which BUCHNER meets by saying that whereas in death as a result of sepsis the spleen is invariably enlarged, this organ was found to be small in all EMMERICH'S cases. It is therefore concluded that the latter has succeeded in isolating an organism in choleraic tissues which is capable of giving rise to a hitherto unobserved malady in animals, and one which corresponds in a marked manner with cholera as observed in man.

It would appear that Dr. BUCHNER has recently had opportunities of practically studying the subject, both at Berlin and Munich; consequently his able contribution carries exceptional weight. Without attempting ourselves to offer any opinion as to the places which these two microbes will occupy in the future as regards their relation to the cholera process, we think that sufficient has been adduced to show that when their respective claims as cholera-causing agents are examined, those of EMMERICH'S bacterium cannot, as the matter at present stands, be set aside, or simply ignored, in favour of the comma-shaped organism.

THE decision arrived at by Sir JAMES HANNEN, sitting as judge and jury in the DURHAM nullity of marriage suit, will be received with general satisfaction by the public and the profession. To those not conversant with the whole of the evidence given *in camera* at the recent trial, it seemed probable that the petitioner would fail to obtain the declaration of his freedom from specific performance of the contract entered into with the respondent. The elaborate and lucid summing up of the judge clearly showed the bearing of that evidence on the main question at issue—did Lady DURHAM at the time of her marriage possess sufficient

intellectual capacity to enable her to comprehend the nature of her acts and the responsibilities entailed by the nuptial vow? There can be little doubt her ladyship's mental equilibrium was none too stable, and that the emotional element in her nature was disproportionate to her willing faculty, but "weakness of mind" is not to be interpreted as "imbecility," nor an expression of doubtful import as proof of insane delusion. Sir JAMES HANNEN struck the keynote of this domestic drama when he declined to be guided by the precedents recorded in other cases that had come within the cognisance of the law, and declared that the present action was eminently one to be decided upon the special facts before the court.

The closing speech of the counsel for the petitioner was a rare specimen of forensic talent, brilliant in its conception, faultless in its logic, and yet it failed to carry conviction to the minds of those to whom it was addressed, simply because the basis of the argument was hypothetical and frail. Sir FARRER HERSCHELL sought to establish his case on analogical reasoning, to prove in fact that Lady DURHAM'S demeanour before marriage might be read by the light of subsequent events. We do not for one moment assert that such a conclusion was inconsistent with the facts, but then it was incumbent on those who undertook the burden of proof to show that no other theory fitted the facts. This was the *crux experimenti*, and before it the astute Solicitor-General was hopelessly defeated.

Because Lady DURHAM comported herself with unwonted shyness and stood impassive to the blandishments of society, was it to be held as truth that she was "not guilty of a second idea?" She might not have had the iron nerve and strength of will accorded to "the man silent in seven languages," but she certainly—so far as the sworn testimony goes—was sufficiently self-possessed to convince a large number of her friends and acquaintances that she was not the subject of mental alienation. Sir WILLIAM GULL during a professional interview failed to recognise more than derangement in bodily health, and it is not likely that so shrewd an observer would have entirely overlooked even the forecast of insanity. There were some incidents in her history previous to wedded life that savoured of suspicion, but even they could not be taken as the indication and measure of imbecility. We refer to the alleged insensibility to pain and to the expression "something too dreadful to tell." With regard to the former, it may be said that the patient endurance of suffering is not the least of woman's many admirable endowments; and further, that the natural susceptibility to one form of nerve stimulation may be minimised or inhibited by a more powerful agency without calling into requisition the theory of disordered intellect. Sir JAMES HANNEN, reading obvious facts and facts between the lines, found sufficient to convince him that Lady DURHAM'S conduct towards her future husband was dictated rather by remorse than by the love she feared to obtrude; and disinterested observers must in the main coincide with his belief. Granted Lady DURHAM was not endowed with transcendental powers of mind—granted, if it be wished, that she was positively weak in this respect—it yet remains to be shown that she overstepped the frontiers of insanity ere she joined her fate with that of Lord DURHAM.

It might be argued, since Lady DURHAM is a confirmed lunatic, and his lordship has lost immediate prospect of an heir to his title and property, that the benefit of the doubt should be conceded to him. Against this is the abstract principle of "legal right," and the possibility that Lady DURHAM'S reason may return. The latter contingency, remote though it be, is yet too important to be lightly put aside. But beyond the interests of those more immediately concerned in the issue of the recent trial, there are lessons to be gathered from a contemplation of the narrative that every member of the community will do well to take to heart. It would be a fatal precedent to establish if something more than the average shyness of girls were to be regarded as an index of mental weakness. The charm and grace of the gentler sex would lose much of their fascination if tinctured with undue boldness of resolution and pretentiousness that mocks at modesty. Our code of social morals is not so rigid that it can afford to give up with impunity one of its most honoured precepts. We fear it would be wasting words were we to attempt to preach wisdom to future worshippers at the temple of hymen. Unfortunately each one prefers to learn from his own experience, and ignores the fate of others.

THE value of vaccination is one of the most important questions which can engage the attention not only of the existing Parliament, but of all those gentlemen who hope to be members of that coming Parliament which is expected by so many to bring about a sort of millennium. We have lately seen two honourable members, those representing South-East Lancashire, entering into reasonable conference with that small but somewhat noisy section of their constituents who have such a kindly feeling towards small-pox. The example cannot be too much commended. The objections to vaccination have a dash of plausibility in them. There is in all of us a certain amount of natural dislike to introduce into the organism that which disturbs and disorders it for a few days, and in rare cases weeks. We do well to give credit to objectors for being willing to reason on the subject, though to extreme vaccinophobists it is sometimes difficult to accord this credit. He is the best friend to vaccination who studies it, and all the objections to it, and all the reported cases of ill results from it. Mr. LEAKE, elsewhere in our columns, shows us that this is his view. He wants us to tell him for what particular proposition as to vaccination we are to feel grateful to JENNER? Not for any particular proposition, we reply, but for his shrewd insight into the relation of cow-pox and small-pox, and for placing the question of vaccination as a protective measure on a scientific basis. Neither JENNER'S fame nor our gratitude to him is materially affected by the fact that some of his opinions and estimates have had or may have to be modified—as, for example, the sufficiency of one vaccination or the relation of cow-pox to "grease." JENNER'S fame—his claim to the eulogy of RUDOLPHI, "Dear to the human race"—lies in the fact that by his experiments, by his resistance to opposition and to the faint encouragement of his friends, even of JOHN HUNTER, he succeeded in placing vaccination on such sure ground that after the lapse of eighty or ninety years it excites the admiration and

gratitude of mankind. It is no detraction from GEORGE STEPHENSON that the locomotive which now takes us to Newcastle in six hours is a more perfect engine than that which he first suggested for the Stockton and Darlington Railway. Equally it does not lessen the fame of JENNER that time shows two vaccinations to be better than one, as future time may possibly show that three may be better than two.

Our main purpose to-day is to direct attention to one or two pieces of recent evidence in regard to this great argument, and especially to "An Analysis of 10,403 cases of Small-pox,"[1] by Dr. W. GAYTON. The chief merits of this pamphlet are, first, in the eminent reasonableness of the author, in his obvious wish to make every allowance to opponents; and, secondly, in the enormous experience on the strength of which he speaks. There is one illustration of his candour which will delight even the irreconcilables in this controversy—the demonstration that the majority of the cases which come into the small-pox hospitals are those of persons who have either been vaccinated or are said to be vaccinated. Of the 10,403, 8234 answer to this description, while 2169 were unvaccinated. "Said to be vaccinated," Dr. GAYTON points out, is one thing, and the possession of visible marks of "due and efficient" vaccination is quite another. Dr. GAYTON found in the 8234 that only 907 were protected in such a way as to warrant their being classified as "well vaccinated," or vaccinated in that way which, *according to our present experience*, confers practical, but by no means absolute, exemption from the disease till the age of puberty is reached, though Dr. GAYTON would perform the operation of revaccination at a much earlier age, as we shall presently see.

Having illustrated the candour of our author, let us now hear what he has to say as to the lessons of his large experience, even of the imperfect success of our first vaccinations. Does he think less of vaccination? Does he aver that the old disease has lost its terrors? Does he despair of absolute triumph over it? Or would he be willing, in consideration of the imperfection of much of the past vaccination work, to abolish the vaccination laws or the compulsory clauses thereof? The answer to these questions will be given in a few sentences, for we expect that our readers will be content with nothing less than the possession and perusal of Dr. GAYTON'S pamphlet.

Vaccination, even when followed by small-pox, is of enormous value. Dr. GAYTON entirely confirms Mr. MARSON'S experience that it powerfully modifies and mitigates the disease. The mortality of those who take small-pox in an unvaccinated state—and it must be remembered that the great majority of such, probably nine-tenths, do take it—Dr. GAYTON'S tables show to be, for all ages, 45·2 per cent. in males, 40·8 per cent. in females; for ages under five years 56·5 per cent.! So much for the boasted influence of hygiene and sanitation on the poison of small-pox, which positively mocks those who rely on such protection. On the contrary, the mortality of the vaccinated cases is as follows:—Of those "with good marks, irrespective of number of marks," 2·6 per cent.; of those "with imperfect marks, irrespective of number," 9·37 per cent. Surely this is no mean result, and would itself justify the Vaccination Laws. But the case of vaccination is not complete without considering the *absolute security* of those who have been well revaccinated. And here we cannot too explicitly repeat our insistance on the necessity for a revaccination that "takes," even though the patient has to submit to several failures before success is reached, which will be rarely the case if good lymph in good quantity is used soon after being taken. One of the best things about Dr. GAYTON'S paper is his discussion, in the light of his large experience, of the time when a vaccinated person becomes again susceptible to small-pox, in other words, when he needs to be again vaccinated. We give his opinion in full:—"The propriety of revaccination, even at all ages after five, cannot admit of much doubt, more especially as the process cannot be considered as a disease, so trivial are the symptoms attendant on it, and so protective apparently is the result." He repeats a description of the experience of Mr. MARSON as to the absolute immunity of the nurses of small-pox hospitals from small-pox. In the Highgate Hospital this has been shown recently by Mr. GOUDE, in the *Islington Gazette*, to extend over fifty years, with only one exception, that of a temporary gardener, who, refusing to be revaccinated, took the small-pox, and died. Of Mr. GAYTON'S large number of nurses and other employés (367) in the Small-pox Hospital, only one has taken the disease (and in her case the operation was neglected). The exceptions terribly prove the rule here. With an excessive desire to be just, Dr. GAYTON adds that possibly the revaccination of small-pox nurses might be shown to be not good for all time if they were traced after leaving the hospital. But this is for the future to show. Enough that according to present evidence it is absolute in the very face of the intensified form of the small-pox poison. Even so it would not materially modify the verdict of time and science that in vaccination well done, and done repeatedly, there is an absolute protection at a very slight cost from one of the most deadly and terrible of diseases. If there is one defect in Dr. GAYTON'S admirable pamphlet it is the absence of details as to the evil or inconvenient results of revaccination. But he incidentally seems to show that these have been too slight to afford the poorest argument for its neglect, and he "simply shudders at the idea of a repeal of the Compulsory Vaccination Act."

[1] Published by McCorquodale and Co., Cardington-street, N.W.

IT would be difficult to predict the shape which the movement for a Teaching University in London and for granting degrees to London medical students will finally assume, but it is at any rate quite evident that it must cause a material change in the constitution and the traditions of the existing university. The tradition of "maintaining the highest attainable standard of professional acquirements" is well enough for an honours degree, but for a mere pass qualification, "to fit its possessor to become a highly qualified General Practitioner" (we quote the words of the Registrar) such a standard is absurd. This policy has done much to ruin our English medical schools, and to send students to Scotch and provincial universities for the degrees which are now fairly demanded by the average practitioner. Our forefathers were satisfied with the

College and Hall qualifications, but, naturally enough with the spread of education, their sons, for the same position in the profession, aspire to a degree. It must not be forgotten that the profession occupies at present a very different position from that of fifty years ago, and is manifestly increasing in influence and in its responsibilities every day. A higher educational status is thus made imperative on every practitioner, and he consequently demands the outward token and sign of this higher standard. Everywhere but in London he can obtain a degree on fair terms of knowledge, and with adequate industry; in London only is the task made as severe as possible. In London 39·6 degrees are on the average obtained yearly, in Edinburgh 137·4; in England 12·4 per cent. of students obtain degrees, in Scotland 86·9. In England the number of students in 1871-75 was 3143, whilst in Scotland there were only 1767 during the same period. Yet 1536 degrees were given by the Scotch universities, and only 402 by the English. It is often urged that Scotch degrees are too easily obtained, but no one who has been through a Scotch University course will seriously maintain that it does not, both in general education and in technical skill, secure a fair minimum for a university degree. Scotch qualifications and Scotch degrees are too frequently confused in the public mind, and hence remarks which may have been just, so far as the former are concerned, have been erroneously supposed to be applicable to the latter. The Metropolitan Counties Branch of the British Medical Association appointed a Subcommittee to consider the subject of University degrees for London medical students, and on the 6th inst. a valuable report was placed before the members. As will be seen in another page, the Council will petition the Senate of the University of London to receive a deputation in support of the objects aimed at in the report, which are the following:—

"1. The Medical Schools of London should be adequately represented in the Senate of the University, the members for the Schools being elected by the Schools. 2. All students save those who have already matriculated at other universities might be required to pass the Matriculation Examination of the University of London previous to entering at the London schools. 3. The matriculation examination might be modified, so as to cover such a range of knowledge as might reasonably be expected from boys on leaving public schools, without compelling them to resort to the most objectionable system of 'cramming.' 4. The severity of the Preliminary Scientific Examination might be considerably diminished. 5. The Preliminary Scientific Examination might be held at least twice a year. 6. Students should be permitted to present themselves for examination at any periodical examination after matriculation. This is of importance; for the result of the present system is that men, contrary, it is true, to the regulations of the University, often spend the first year of their hospital course in preparing for the preliminary scientific examination, and thus lose a great part of that period which should be given to purely professional purposes. The subcommittee would, moreover, recommend that the Senate of the University be requested to take into consideration what arrangements, if any, could best be made, without detriment to medical education, whereby facilities to obtain degrees should be afforded to medical practitioners of certain standing and repute."

If the Senate of the University cannot see its way towards granting these objects, and the pressure of the Teaching University and the Committee of its own graduates may make it think twice before refusing them, the Council is empowered to take action, in conjunction with the Royal Colleges, to facilitate the obtaining of degrees by London students. Will the wise action of the executive authorities of the existing University avert the necessity of creating a rival body in London, or must there be a second University—which everyone would deplore—because of the obstinate optimism of those who control the affairs of the present institution?

EXTIRPATION of the uterus is an operation undertaken mainly for cancer, and although it has been performed for other conditions, yet it is as an operation for the radical cure of cancer it must stand or fall. In discussing it, therefore, many things must be taken into consideration besides the immediate mortality resulting from it. The operation may be a perfectly legitimate one, although the mortality be very high, but only if its curative results be well nigh perfect; if the mortality be moderately low, and the results as far as cure moderately good, the operation may still be justified. On the other hand, if the immediate mortality be very high and the results as to radical cure bad—that is, if recurrence be frequent and the mortality during the first six or twelve months high, if permanent recovery and even prolongation of life be rare, and if the relief of suffering be slight or even doubtful,—then the operation of total extirpation of the uterus for cancer should be unequivocally condemned. This subject has been recently discussed at the Obstetrical Society, and the weight of evidence brought forward appears to be in nowise favourable to the operation of total extirpation of the uterus. A paper by Dr. WILLIAM DUNCAN formed the basis of the discussion. The author had collected 413 cases in which the operation had been performed; 137 of these were done by the abdominal or FREUND'S method and 276 by the vaginal method. Of the 137 operated upon by the abdominal method, 99, or 72 per cent., died, and only 38 recovered; and of the 276 operated upon by the vaginal method 79, or 28·6 per cent., died. The discussion threw no new light on the methods of operating, but the statistics contained in the paper clearly showed that the vaginal is far less fatal than the abdominal method. The mortality from the abdominal method is alone sufficient to condemn that mode of operating. If evidence against it still more damaging than a mortality of 72 per cent. is demanded, it is to be found in the fact that the ultimate results after it are just as bad as after the less fatal vaginal method, and even worse than the so-called palliative method—supravaginal amputation of the cervix. The mortality by the vaginal method is high, probably considerably higher than 28·6 per cent.—the rate obtained in the cases collected by Dr. DUNCAN,—because many fatal cases remain unpublished. This rate of mortality, however, may not be such as to condemn the operation, provided that the favourable results mentioned above as necessary to justify an operation with a high mortality are obtained. Now, what are the ultimate results of total extirpation of the uterus for cancer? The immediate results are 72 per cent. mortality after the abdominal and 28·6 per cent. after the vaginal method. Although there is an enormous difference in the immediate results in favour of the vaginal method of operating, there is no such difference in the ultimate results, for it is found that 32 per

cent. of those who recover from the operation were free from recurrence two years afterwards. This means that of the 137 cases operated upon by the vaginal method 121 die within about two years and a half; and of the 276 operated upon by the vaginal method 214 meet a similar fate within a like period. About a third of the cases show recurrence within six months, and a half within a year of the operation. To justify the operation for total extirpation of the uterus the formerly high mortality of ovariotomy is pointed out and its recent reduction. It is true that the immediate mortality after the vaginal method is not much greater than that after ovariotomy was until about ten years ago; but ovariotomy differs from total extirpation for cancer in that it is a radical cure, while a large number of those who undergo the operation for total extirpation of the uterus perish within a few months of recurrence of the disease. The two operations are not comparable. Moreover, the palliative operation—amputation or supra-vaginal amputation of the cervix—with a mortality of about 10 per cent., is followed by ultimate results even better than those obtained by total extirpation—namely, 32 per cent. of the cases which recover remain free from recurrence two years afterwards; a fact pointed out in our columns on a previous occasion. This means that out of 100 cases operated upon by supra-vaginal amputation of the cervix 90 recover, and 27·8 remain free from recurrence after two years; whereas of 100 cases in which total extirpation by the vaginal method has been practised, 71·4 recover and 22·8 remain free after two years. If, however, the actual cautery be used to the stump after amputation of the cervix, the results are still better: for out of every 100 operated upon, 37·8 remain free from recurrence after two years. These facts show clearly that the results following vaginal and supra-vaginal amputation for cancer of the cervix are twice as good as those after total extirpation of the uterus for the same disease. The opinions expressed in the recent discussion were almost unanimously against total extirpation for cancer of the cervix. With regard, however, to the same operation in cases of cancer affecting the body of the uterus there was considerable difference of opinion—some being in favour of, while others were opposed to it. The data for forming an opinion with regard to the value of the operation in this condition are somewhat scanty; and as a rule no distinction has been made in them between operations performed for cancer of the body and those done for cancer of the cervix. The great majority of the cases in which total extirpation has been practised have been cases of cancer of the cervix, while only in a small proportion of cases has it been performed for disease of the body of the uterus. Of seventy-six cases in which total extirpation has been performed by different operators, thirteen only were subjects of cancer of the body of the uterus. Of these thirteen cases five died; recurrence took place in one in three months, in one in four months, in one in eight months; fungosities had to be scraped from the cicatrix in another in eight months; one remained free from recurrence seven months, and another eighteen months, after the operation; and the ultimate result is uncertain in two. One of the thirteen was operated upon by the vaginal method, and the mortality may be considered to represent that of the two methods; deducting this one case, we have a mortality of 33 per cent. of cases operated upon by the vaginal method, while we have recurrence of the disease in three, or 37·5 per cent. of those who recovered, in less than twelve months; and only one is known to be free from the disease eighteen months after the operation for the radical cure. It is known that cancer attacks the body of the uterus, as a rule, in women long after the menopause; that it runs a comparatively slow course; that for a long time it is almost painless; that the pain, indeed, is usually not severe until the disease has made its way into the deeper tissues; that the discharges are frequently neither abundant nor very offensive until the later stages. In many respects the disease is far less intolerable when it affects the body than when it attacks the cervix. The duration of life in it, although not accurately known, is considerable, probably considerably longer than even in those who recover after total extirpation; for if the disease recur in the peritoneum it usually runs a rapid course. No evidence is as yet forthcoming that total extirpation of the uterus for cancer of the body either prolongs life or relieves suffering; while, on the other hand, the mortality after the operation is known to be large, and early recurrence extremely frequent. The facts known unequivocally condemn total extirpation for cancer of the cervix, and are decidedly unfavourable to its practice for cancer of the body of the uterus.

Annotations.

"Ne quid nimis."

PHYSIOLOGY AT OXFORD.

NEVER was defeat better deserved than was that endured by the anti-vivisectionists in Convocation at Oxford on Tuesday last. In an extraordinarily large house the decree for an annual grant of £500 for the maintenance of the newly-erected Physiological Laboratory was carried by an overwhelming majority, 412 voting in favour of it as against 224. All that misrepresentation could do did not succeed in overturning the previously twice-recorded votes of Convocation to found a physiological school in the University. It is painful to think of the manner in which this final attempt has been organised, and of the total disregard of the pledges made by the Professor that no painful experiments will ever be permitted for purposes of demonstration or instruction. Had these tactics been successful the University would have stultified itself in the eyes of the world, and would have practically declared that, although it could disburse £10,000 for providing buildings for the prosecution of physiological education and research, it must decline to permit these buildings to be put to the use for which they were constructed. And with such a decision a blow would have been struck against medical education at Oxford which would have amounted to its practical extinction. Fortunately for the credit of the University its graduates have unhesitatingly shattered the specious and plausible arguments which a small party of enthusiasts employed to cover their ill-advised opposition. In their detestation of the practice of vivisection they did not scruple by their action to imperil the very existence of human physiology as a subject to be taught at Oxford, for the grant proposed had nothing at all to do with animal experimentation; it was merely to afford the necessary funds for carrying on instruction where vivisection would not be required. It is absurd for them to state that there was no intention to

oppose the teaching of physiology apart from vivisection, because there was no other course open than to offer a direct negative to the proposal for the grant; for the logical outcome of such a course could only have been to annul all that had been before resolved. If Oxford University is to have a medical school worthy of itself, and is to be relieved from the reproach hitherto, and not without reason, cast upon it, then no effort should be spared to secure the highest possible efficiency in the departments of study. To Professor Burdon Sanderson we offer our hearty sympathy for the anxiety and annoyance which these proceedings cannot but have cost him, and we deeply regret to observe that some of those who have most urgently fomented the agitation against the decree should have assailed him personally in a manner which has aroused the deepest indignation. Strong conviction may account for much, but it cannot be held to excuse such language as that employed by the leading spirit of the anti-vivisection crusade with respect to Dr. Sanderson; but reckless and unjust statements have been the distinguishing feature of the promoters of a movement which, in spite of the motives at its root, has alienated the sympathy of many by the course that has been pursued to gain its ends. We yield to none in the desire to limit the infliction of pain upon the lower animals, and should wholly discountenance the employment of vivisection for the purpose of demonstration of well-established facts to a class of young students; but it is quite another matter that such men as Professor Sanderson should be prevented from pursuing researches which may lead to incalculable gains to the well-being of the animal world as well as to mankind.

PSEUDO-SCIENTISTS IN RELIGION.

PROFESSOR DRUMMOND, the author of "Natural Law in the Spiritual World," has set up for the apostle of "a new 'scientific' Gospel"—at least that is how Mr. Robert A. Watson characterises this effort of the "Professor" in the current number of the *Contemporary Review*. From the standpoint of those who revere religion while they serve science, the "Gospel" and its *exposure* will appear equally absurd. Professor Drummond evidently has not a very profound knowledge of science—even of the elementary principles of physiology,—while in regard to psychology he is hopelessly in the dark. This is doubtless why, in spite of his manifest general intelligence, he rushes into the breach with pigmy valour where giants have scarcely dared to venture. Mr. Watson would probably find a good deal of his fog cleared away by a careful study of Herbert Spencer's chapters on "Dissolution." One result would be to prevent his further fighting a windmill in relation to the hypothesis of degeneration. It is not worth while to discuss the vagaries of minds disporting themselves in an uncongenial element, and contending in all seriousness and with fervour on points they have not either of them mastered. Professor Drummond strives to prove that the laws of "nature," so-called, are also the laws of the extra- or super-natural; but as he does not understand the laws of nature, and of course knows nothing more than others know of the extra-natural, his enterprise is rather irritating than entertaining. Mr. Watson tries to meet him on his own ground, which, seeing that Professor Drummond has not a particle of solid ground to stand upon, is particularly unwise and useless. Why will not those who waste words on these subjects be candid, and admit that there is a point beyond which we cannot penetrate? The true scientist is—must be, as such—agnostic, not in any sectarian sense of that term, but in a common-sense way, on the subject of all that lies beyond the ken of science. We say nothing as to what may be discovered in the future. One thing, however, is certain: if any discoveries are made, they will not, cannot possibly, be made by speculative philosophers. It is in the pursuit of a calmly progressive inquiry in *physiology* new facts are to be expected. Meanwhile, as regards the origin of life, the nature of the unseen world, the government of this world and the universe, and the future, true science has nothing to say, because data are wanting. Men who venture to touch the outer sphere can only do so "by faith." "It is by faith we understand the world was made," &c. There is no sort of opposition between religion and science, simply because the one begins where the other stops short. They are like two explorers, both advancing, but without one overtaking or treading on the heels of the other. Science deals only with the *known*, religion with the *unknown*.

ARMY MEDICAL SERVICE.

A NEW schedule of qualifications necessary for candidates desirous of obtaining commissions in the Army Medical Staff has just been issued. It is essentially the same as that which it supersedes, except in the following particulars:—The number of marks attainable for chemistry and pharmacy and a practical knowledge of drugs will in future be 1000 instead of 100. The examination in chemistry will be limited to the elements of the science and to its application to medicine, pharmacy, and practical hygiene. A minimum of qualification is established, no candidate being considered eligible who does not get at least one-third of the marks obtainable in each of the compulsory subjects of examination. In each of the voluntary subjects candidates will not be allowed credit for any marks under one-third of those obtainable. The appointments competed for will be filled up from the list in the order of merit, "as finally determined by the total number of marks each candidate has obtained in both the compulsory and voluntary subjects." We regret to observe the omission of any reference to the results of the examination which takes place at the conclusion of the course at Netley. It is, we think, desirable that, as in the case of candidates for the Indian Medical Service, the marks gained in that examination should be allowed to influence the position of the officer on the list.

SANITATION AMONG EAST-END JEWS.

IT may be remembered that shortly after the publication of our special commission report on the sanitary condition of the homes and workshops of the Polish Jews in the East-end, the Jewish Board of Guardians appointed a sanitary committee and a paid inspector of their own to investigate the whole question. Our report appeared in the first week of May and the new inspector commenced his work in the following June. During the course of the year, no less than 1747 houses inhabited by Jews were visited, and out of this number it was found that no less than 1621 had no means provided for the flushing of the waterclosets. Some years ago Dr. Liddle, then the medical officer of the Whitechapel district, expressed the opinion that as the apparatus for flushing closets in low class tenements was so frequently broken, it would be better to appoint a caretaker to periodically flush the drains with pails of water. This, however, is no sufficient excuse for neglecting to provide either flushing apparatus or caretaker. Also, as the Jewish Sanitary Committee justly point out, improved mechanical means of flushing have been introduced since Dr. Liddle expressed the above opinion. In the immediate neighbourhood the City Commissioners of Sewers have supplied water to all the closets provided for identically the same class of population, and there is no good reason why this example should not be followed in Whitechapel. There are in this district 7500 houses, nearly all inhabited by very poor people, who should be subjected to constant sani-

tary supervision, and yet the present medical officer of health, Dr. Loane, has only two sanitary inspectors working for him. Under these circumstances the assistance of such voluntary bodies as the Jewish Sanitary Committee should be welcomed. Indeed, many defects have been remedied without reference to the constituted authorities. A word from the Jewish inspector has sufficed, and it has not been necessary to appeal to the district board. Nevertheless much still remains to be done, notably with regard to the paving and draining of back yards. Here the moisture, a mixture of rain and slop water, is allowed to penetrate into the foundation of the houses. The bell-traps are usually without a bell, and the fall in the level of the yard fails to convey the water to the drain. This, together with the unflushed closets and the uncovered dust-bins, constantly produces foul effluvia, and is denounced by the Jewish guardians. They acknowledge that those among their co-religionists who come from the far East have uncleanly habits, but this is not the case with the English born Jews, while many among the Christians of the lower orders are equally filthy. However this may be, we may, for our own part, state that we found the habits of the Italian organ-grinders quite as incompatible with English ideas of sanitation as those of the Polish Jews. Altogether the Jewish Board of Guardians have shown great public spirit. Mr. D. F. Schloss, the honorary secretary of their Sanitary Committee, has notably contributed by his activity and organising skill to materially improve the sanitary condition of the Jewish colony of East London.

THE PHARMACY OF COCAINE.

MANY pharmaceutical papers, both in this country and abroad, are devoting a large amount of space to the consideration of the best modes of dispensing different preparations containing cocaine. One periodical gives directions for making a "cocaine eye wash," a "coca-styptic," a "coca-styptic powder," a "coca-styptic collodion," and even a 'coca-cordial." What may be the result of the indiscriminate use of these various combinations remains to be seen. Dr. Squibb of New York, in the last number of his *Ephemeris of Materia Medica, Pharmacology, and Therapeutics*, devotes over twenty pages to the subject of cocaine, and, as usual, his observations are both suggestive and amusing. He considers that the hydrochlorate or muriate is by far the best salt. It contains the largest proportion of alkaloid, crystallises with the smallest quantity of water, is very soluble, and is not deliquescent. The salicylate is also a good salt. The solution would probably need no protective agent to keep it, but the high combining number of the acid would give a much weaker product, and one less soluble in water. The process of extracting cocaine is long and tedious, and often results in nothing but disappointment. When set free from its natural combinations in the leaf the alkaloid frequently splits up at a comparatively low temperature, yielding benzoic acid and an alkaloid or glucoside, or both, containing no cocaine, or perhaps only a trace. The yield, too, is subject to considerable variation; for example, the batch of 164 pounds gave ·34 per cent. of the finished salt, whilst from another lot only ·27 per cent. was obtained. The process is expensive not only in time, labour, and apparatus, but in solvents. The actual loss of alcohol is never less than twenty gallons to the hundred pounds of leaves; whilst in addition, from twelve to thirteen gallons of strong ether are consumed. Much of the coca sold in the market, even at high prices, is of variable quality, and often contains no alkaloid at all. The methods of assay have recently assumed much importance, and now give constant employment to a number of skilled chemists. The alkaloid when obtained is easily split up and destroyed by even a moderate degree of heat, and this destruction is materially aided by the presence of chemical substances, especially alkalies. When a particle of the alkaloid is placed upon the tongue, and the tongue is pressed against the roof of the mouth, a bitter taste is experienced. This, in a few seconds, gives rise to numbness and insensibility of the mucous membranes, just as if they had been scalded by boiling water, except that there is no pain. This increases for a few minutes, then diminishes slowly, and finally disappears in about half an hour. Solutions containing cocaine are liable to the attacks of a fungus, which lives on it and quickly destroys it. We may, however, call attention to the letter of a correspondent on another page in which it is recommended that the cocaine solution be filtered through animal charcoal, and a few grains of salicylic acid added to it, in order to preserve its efficiency. The growth commences usually in about a week, and when once started increases with great rapidity. Several antiseptics—carbolic acid, boracic acid, and salicylic acid, for example—prevent its formation, but they are all more or less irritating, and some exert a most injurious effect on the conjunctiva. An additional objection to salicylic acid is its extreme sensitiveness to even minute traces of iron, so that it is almost impossible to get a colourless solution. The demand for the alkaloid is still very great, and it continues to command high prices. The chief maker in Europe is Merck, of Darmstadt; but in America it is extracted in considerable quantities by several chemists.

ADDISON'S DISEASE.

AT the meeting of the Berlin Medical Society on the 25th ult., Dr. Jürgens showed specimens obtained from two cases of Addison's disease. One exhibited the typical characters of the adrenal affection, together with caseous bronchopneumonia; the other was a case which had been under observation for some time, presenting the clinical symptoms of morbus Addisonii; but it was a case in which a large aneurysm of the abdominal aorta had compressed the splanchnic nerves. The statement was made that in all cases of Addison's disease these nerves are in a state of grey degeneration, and that cases in which the adrenals are diseased, without any discolouration of the skin or other clinical symptoms of Addison's disease, these nerves are not involved. The account (*Deutsch. Med. Woch.*, March 5th) is too meagre to allow of any criticism upon this communication; but it is to be hoped that full details (clinical as well as pathological) will be published.

CORONERS AND MEDICAL EVIDENCE.

CORONERS, especially legal gentlemen holding that office are by no means always ready to show sufficient regard for medical men who may chance to be attacked by witnesses or jurors, or to give due weight to the testimony which they, and only they, can give regarding the cause of death. It is therefore gratifying to record the sensible manner in which the Rochester coroner, Mr. W. H. Bell, LL.B., conducted an important inquest on the body of a furnaceman employed at the Chatham Dockyard. It was stated that deceased had complained for five months of pain in the head, but had not been medically attended since the previous spring, when he was in hospital on account of an injury received while at work. After this he had been at work, but always complained of his head, though he had never done so previously. A doctor was sent for, being told the man was dying, and he said he would come next morning. A remark was here made that "it was a nice thing for a doctor to say he would come to-morrow when a man was dying," and that the circumstance ought to be explained. The coroner, however, said he would not allow any remarks to be made about medical gentlemen unless they were present, and that a doctor was not bound to leave one patient

for another. The medical evidence was that, though there was a scar on the scalp, and under it the bone was indented and the membranes inflamed, thickened, and adherent, yet that this was insufficient to account for death, which was due to a fibrous tumour deeply situated and remote from the external mark; this growth weighed four ounces and three quarters, and was as large as a good-sized orange. Several of the jury were of opinion that the death was brought on by the blow received. The coroner, however, informed them that they must go by the medical evidence; that if not they might as well dispense with medical evidence at inquests altogether; and ultimately a verdict was returned to the effect that death was due to a tumour, but accelerated by injury.

MEDICAL SOCIETY OF LONDON.

THE dinner celebrating the 112th anniversary of the Medical Society of London took place on the 7th inst. at the Holborn Restaurant. The retiring President, Mr. Arthur E. Durham, occupied the chair, and was supported on his left hand by the President elect, Dr. W. Miller Ord, and on his right by Mr. Cooper Forster, President of the Royal College of Surgeons of England. The dinner was most successful in every way, about a hundred Fellows of the Society being present. Mr. Durham, in proposing the toast of "The Army, Navy, and Reserve Forces," referred to the offers of aid which the British Government had received from the colonies, and made reference also to the excellence of the arrangements of the Army Medical Department now serving in the Soudan, so that now, he believed, every wounded man was attended to immediately on the receipt of his wound. Dr. Crawford, Director-General of the Army Medical Department, in replying to the toast, spoke in highly satisfactory terms of the arrangements for the medical and surgical care of the army in the Soudan, and referred to the great services which the Medical Department had already performed, special mention being made of Surgeon-Major Conolly. The toast of the evening, "The Prosperity and continued Success of the Medical Society of London," was responded to by Dr. Miller Ord. Mr. Cooper Forster and Sir Joseph Fayrer did the honours of the toast to "The Royal Colleges of Physicians and Surgeons." The toast of "The President" was received with loud and prolonged applause; and Mr. Durham, in acknowledging the toast, said that his year of office had been a source of much pleasure to him, and he had to thank the officers, and more especially the honorary secretaries, for the cordial and able support which they had afforded him on all occasions. The last toast, that of "The Officers and Honorary Secretaries," was responded to by Dr. Allchin, Mr. Pearce Gould, and Dr. Kingston Fowler.

CHOLERA VACCINIA.

SOME interesting and important experiments with attenuated cholera virus have been made by Dr. Ferrán of Barcelona. Two medical men, Drs. Serañana and Jacques, were inoculated with the virus. At 5 P.M. the former was inoculated with half a cubic centimetre of the fluid in each arm. At 7.30 he began to feel severe pain in the backs of the arms, preventing their free action. This pain was subject to temporary exacerbations, and at 11 P.M. pyrexia commenced—we are not told whether the thermometer was used,—manifested by malaise, a burning heat, an irregular pulse of 100 per minute, insomnia, and slight headache. He was, however, able to attend to his practice the following day, though the symptoms continued till 8 o'clock in the evening, when they suddenly disappeared. Dr. Jacques was inoculated with half a cubic centimetre of the same fluid in one arm at 4 P.M., and experienced the same symptoms as his colleague, with the addition of a slight rigor and some nausea. Dr. Bertran y Rubio also, a member of the commission appointed by the Royal Academy of Medicine to investigate Dr. Ferrán's researches, willingly submitted to inoculation, and with results similar to those obtained in the cases of Drs. Serañana and Jacques, and like them without any subsequent evil effects. These experiments form part of a series of micro-biological researches suggested by the Royal Academy of Medicine of Barcelona, and they were performed in the presence of the commission, to whom Dr. Ferrán exhibited a microscopical preparation of the liquid injected and of Dr. Serañana's blood eighteen hours after the inoculation, in which micrococci were detected. Dr. Ferrán also put a couple of drops of the liquid attenuation into half a glassful of water and drank it. In order to render these experiments complete, it remains to be proved that such inoculations confer immunity from subsequent similar inoculations, and, what is of more importance still, from inoculation of the cholera virus itself. These researches are to be shortly undertaken; and the *Independencia Médica*, to which we are indebted for the above account, predicts that Dr. Ferrán will be successful in his attempts to free mankind from cholera and other contagious diseases by means of inoculations of attenuated virus.

PHARMACEUTICAL SOCIETY OF IRELAND.

THE advisability of forming a school of Pharmacy in connexion with this Society is now under consideration, and although the Council are favourable to such a scheme yet they have no funds available for starting an institution of the kind. It has, therefore, been suggested to form a limited liability company with a capital of £1000, and a committee has been appointed to bring the matter under the notice of the pharmacists and apothecaries of Ireland, with a view to obtain their support. It is believed that such a school, in which evening instruction would be given at moderate charges in practical chemistry and materia medica, would supply a want long felt.

THE PRESTON SANITARY ASSOCIATION.

WE have so frequently during the last few years had occasion to call attention to the high death-rate in Preston, and to the waste of life and health which it signifies, that it is only natural we should cordially congratulate the town upon recent signs that it is awakening, though somewhat tardily, to the vital importance of its sanitary condition. The formation of the Preston Sanitary Association, with an influential support which promises a career of usefulness, is undoubtedly a step in the right direction. The discussion which took place at the preliminary meeting of the Association on the 9th ult. at least shows that the high death-rate in the town has attracted the attention of those who, if they keep their hand to the plough, will have no difficulty in removing the stigma which now attaches to Preston, as one of the three most unhealthy towns in England. It may be well again to point out that during the last three years the death-rate in the borough has averaged 26·8 per 1000, whereas the mean rate in the same period in the twenty-eight large English towns has not exceeded 21·8. This means an excess of more than 500 deaths each year in Preston, without regard to the inevitably accompanying excess of sickness implied by the unnecessarily high death-rate. The discussion undoubtedly pointed to the want of sound statistical information regarding the mortality in the town. The ever-green fallacy of a high birth-rate causing a high death-rate had its advocates; and some of the speakers made somewhat random assertions as to the mortality at different ages, and of the two sexes, from different causes in Preston, pointing to the want of scientifically constructed mortality statistics for the

town, without which the causes of the excessive mortality cannot be properly ascertained and differentiated. This should be the first aim of the Association. The second should be to secure the election of a town council and sanitary authority that will appreciate at its proper value the primary importance of the health question to the welfare of the town.

A LOCAL GOVERNMENT BOARD INSPECTOR AT TUNBRIDGE.

MR. SPEAR, one of the Inspectors of the Local Government Board, who recently called the attention of the Woolwich Local Board to the deficient arrangements for combating a possible epidemic in that place, has been paying a visit to Tunbridge, and after inspecting the district had an interview with the sanitary authority. He said "he had during the last few days visited certain parts of the district in company with the medical officer of health, and he considered that immediate steps should be adopted to meet the danger of a possible invasion of cholera. In the first place prompt notice should be given of any suspicious case, and steps taken at once for its isolation. For this purpose they should have one or two cottages which had round them plenty of room in which to erect tents." He then mentioned specific instances of defects in various villages, and suggested remedies. The members of the board explained some of the difficulties they were labouring under with regard to some of the villages, such as difficulty of disposing of sewage, insufficiency of water, &c. In one case it was stated that the Local Government Board itself had listened to the landowners, and decided against the grant of a small site for sewage works. The medical officer of health, Dr. Butterfield, in whom Mr. Spear said that he had every confidence, explained that he had advised every gross case of nuisance to be removed, a house-to-house inspection, provision of an infectious diseases hospital, and the continuance of a system of giving diarrhœa medicine, which had been already in operation, with a beneficial result. It would be well if such discussions as this, which can do nothing but good, were more frequent.

PROF. VIRCHOW ON CROUP AND DIPHTHERIA.

IN a speech recently made at the Berlin Medical Society, Professor Virchow restated the views he has long held upon the pathological dissimilarity of croup and diphtheria; and the statement from such an authority must command attention, although it is hardly consonant with conclusions which have been mainly accepted in this country since the report of the Royal Medical and Chirurgical Society's committee was published. Virchow briefly reminded his hearers that the term croup, originally a clinical phrase expressive of a prominent symptom of acute laryngeal affections, was first applied in a pathological sense by Rokitansky to all pseudo-membranous affections of mucous membranes, and extended by him to visceral inflammations characterised by fibrinous exudation. In 1847 Virchow, in the first volume of his *Archiv*, pointed out the anatomical distinctions between a croupous and a diphtheritic inflammation of mucous membranes, the former being an exudation upon the surface of the membrane, the latter a necrotic process, in which the false membrane is composed of the exfoliated tissue. At that time he knew nothing of micro-organisms in connexion with diphtheria, but he had observed masses of granules, as he then supposed of albuminous nature, in the substance of the diphtheritic membrane, which were never present in the croupous exudate. Nor has he ever been enabled to admit that all cases of fibrinous laryngitis and tracheitis are due to diphtherial poisoning, and he had preparations in which there was not the least evidence of diphtheria. His contention was that the diphtheritic process invariably led to destruction of the mucous membrane, and this recognition of an anatomical difference between croup and diphtheria was, he thought, of prime importance in regard to prognosis after tracheotomy, for in the one case detachment of the false membrane did not, as in the other, leave any ulcerative lesions behind. In support of this he showed preparations of diphtheritic laryngitis and tracheitis with ulceration.

CHRIST'S HOSPITAL SCHOOL.

WE think few will be found to cavil at the comprehensive and judicious scheme presented by the Charity Commissioners for the future administration of Christ's Hospital. Without entering into all the details concerning the administration of the funds of the charity, the appointment of governors, and other general provisions, we would especially commend the resolution arrived at to remove the school, as it at present exists, from London to a country site, not yet determined. This course THE LANCET has specially insisted on for years, and it ought to have been carried out long since, for its removal could have been effected without the intervention of the present elaborate scheme. Many of those who received their education at Christ's Hospital have recorded their experiences, and in after-life have expressed themselves strongly on the cruelty of having thus been confined in the heart of a large city, instead of being allowed to grow strong in the pure country air. The late Professor Parkes felt very deeply on this point, and partly attributed his delicate health in after-life to this cause. Charles Lamb has also recorded his experiences of a Bluecoat boy's life in no favourable terms, and that too at a time when it was possible on a holiday for adventurous spirits to reach the green fields in the neighbourhood of London for a few hours. Now that the school is to be removed, the next question to be considered is where it shall be placed. Some are in favour of utilising the buildings at Hertford, which have been used as a preparatory school for younger boys before they were sent up to Christ's Hospital. But against this it is urged that, as the school is to be moved from London, it is advisable to secure a real country site. In a small country town there would be great difficulty in securing freedom for the boys without bringing them into contact with the townspeople, and thus running the risk of having any epidemic prevalent in the town imported into the school. On the other hand, if the boys are to be cooped up in a playground, half of the advantage gained by their removal from London would be lost. The question of site is an all-important one, and will, we trust, not be decided upon hastily or without sufficient deliberation.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

AT a meeting of the Council of this body held on the 5th inst., a resolution, proposed by Dr. Charles Cameron, Vice-President, was carried, to the effect that a clause in the new Charter should be added to admit *ad eundem* Fellows, Licentiates, and Members of the London and Edinburgh Colleges. These Colleges have power in their Charters similar to that now sought to be obtained by the Irish College of Surgeons.

THE PROSPECT OF MEDICAL LEGISLATION.

WE do not gather that the Government has come to any decision on the subject of Medical Legislation. There can be little doubt that both the Lord President and the Vice-President of the Council would like to see the Bill on which they have spent so much time and trouble passed. But in the present state of public affairs the refined obstruction by which they have been hindered should be withdrawn before they introduce another Bill.

THE VALUE OF AN ISOLATION HOSPITAL.

THE story which is told from year to year in the successive reports of the Delancey Isolation Hospital at Cheltenham is one that should act as an incentive to populations of those towns which have as yet failed to provide similar means of sanitary defence. The Delancey Hospital had its origin in a munificent gift to the town, and it is still to an important extent maintained by public contributions, but in the work which it effects it essentially resembles an infectious hospital provided by a sanitary authority. The record of its work as to small-pox alone is in itself most important, and it is the more so because Cheltenham is a town which has at times by serious neglect of vaccination rather prepared itself for the reception and diffusion of the small-pox poison, and it is doubtless to the instant means of isolation which are always available that its escape from a serious epidemic is due. For eleven years the Delancey Hospital has been in existence, and during that period twenty-two distinct outbreaks or importations of small-pox have occurred. Removal to hospital has invariably been resorted to, and the result is that the disease has never spread beyond the house into which it was first introduced. During the past year two cases were imported into Cheltenham, and the effect of immediate isolation was as satisfactory as in former years. The hospital has also been of immense value in the isolation of scarlet fever, and it is much to be regretted that, for lack of funds wherewith to provide increased accommodation, it has on two occasions been compelled to close its doors against patients coming from the Cheltenham Town Council and the Local Board of Leckhampsted, both of which bodies make a limited use of the hospital for their districts. The original scheme was to make much larger provision for scarlet fever cases than has yet been possible; and having regard to the sanitary aspects of the hospital, we should be glad to see the two authorities who use the building combining for the purpose of making a substantial permanent addition to the accommodation at present available.

PROFESSIONAL SECRETS.

OUGHT the medical adviser of a patient to betray the secrets confided to him? Without hesitation or reserve we say "No," in so far as those secrets *are confided by the patient.* For example, the manner in which a patient contracted a particular malady, and the errors of life that led to it, being confided by the patient, are matters communicated in confidence, and that confidence ought not to be abused. No court of law can exercise any legal right to extort such secrets. Meanwhile, the fact that a patient suffers, or has suffered, from a disease of body or mind is not a subject of communication. The medical practitioner diagnoses the disease, and we do not think that such facts are "secrets," although no honourable man would mention them unless compelled to do so.

THE BRESSA PRIZE.

THE Royal Academy of Sciences of Turin has notified that the period of competition for the fifth Bressa Prize extends from Jan. 1st, 1885, to Dec. 31st, 1889. The value of the prize is £480 (12 thousand lire). All Fellows of the Turin Academy are excluded, but otherwise scientific men of all nations are eligible. The prize will be awarded by the Academy to the scientist who within the four years stated (1885-89) shall have made the most notable and useful discovery, or produced the most celebrated work, on physical and experimental science, natural history, pure or applied mathematics, chemistry, physiology, and pathology, geology, history, geography, or statistics. Whatever defects the programme may possess, narrowness is certainly not one of them.

PENNY DINNERS.

THROUGH the kindness of the hon. secretary of the Council for Promoting Penny Dinners we have received a pamphlet giving much useful information as to the working of this new effort of school management. Since its first establishment at the village schools of Rousdon and Farnell the application of the system has sufficiently extended to allow of some general idea being formed as to the results attained, and these have not been less satisfactory than they at first promised to be. Marked improvement in health, better school work, more regular attendance, and apparently less illness (though there is some doubt as to the latter gain) have distinguished the children who have thus been made sure of one good meal a day. At home the freedom from dinner cookery has proved a boon to many working parents. Valuable hints will also be found in the report before us as to the minor details of time, place, marketing and choice of material, advertisement, assistance, and administration generally, the clear and practical observance of which is all-important for success in a work of this kind. Recipes are quoted *in extenso.* The bulk of the components of these are of course vegetables, bread, potatoes, and peas holding a deservedly prominent place. Meat, however, is not forgotten, nor is milk. It is calculated that each child receives about twelve to fifteen ounces of soup, stew, or other forms of nutriment per meal; and one may say that this quantity contains as a rule an ounce to an ounce and a half of meat, along with a third to three-quarters of a pound of solid vegetable matter. The children enjoy such meals, as well as thrive on them; and when one considers how much more scanty, unpalatable, and expensive is the meal which some of them have at home, it is surprising that the system is not more widely known and practised than it is. The pamphlet we have mentioned is published by Messrs. Alexander and Shepheard, 21, Castle-street, Holborn, and is cheaply purchased at one penny.

"FALSE IMPRISONMENT IN THE LUNATIC WARDS OF A WORKHOUSE."

A MRS. HICKS has obtained £250 damages against the authorities of Marylebone parish for her forcible removal to the workhouse and detention there as a reputed lunatic. The law requires that persons suspected of being lunatics should be brought before a magistrate within three days. The lunacy laws are bad enough, but this case was not a case of bad law, but of bad practice, and the two should not be confounded. The error made was in not having the order for detention duly signed by Justices of the Peace. The course taken is inexplicable.

EVACUATION OF THE FEMUR.

IN the last bulletin of the Royal Academy of Medicine of Rome (Dec. 28th, 1884) is recorded by Dr. Tassi the case of a girl aged thirteen, the lower third of whose femur he had successfully evacuated for fungous osteo-myelitis. When eleven years of age she began to suffer such excruciating pain in the outer condyle of the left femur that she was obliged to keep her bed. The part swelled very considerably, and became the seat of an abscess, which was emptied by the surgeon. An osseous fistula remained, and through it the probe passed from the outer to the inner condyle, with a good deal of hæmorrhage from the fungosities. Opening of the sinus, and cauterisation of the fungous cavity during seven months, proved useless. Dr. Tassi was thereupon induced to lay the femur freely open, and to evacuate it with the gouge, from the outer condyle to nearly the middle of the thigh bone. The epiphysis was evacuated with the spoon, so as to leave only a thin shell of bone. The bony

cavity was filled with iodoform, and the limb immobilised in a plaster-of-Paris apparatus. For the sake of cleanliness the plaster case was renewed at the end of sixty-two days. The patient had no febrile symptoms; and complete recovery, with bony repair, was obtained in the space of six months.

IS "OVERLAYING" INFANTICIDE?

IT does not affect the question of killing, whether a child be overlaid intentionally or accidentally. The only question that can be raised in any case is, whether the act of killing was accidental, or malicious, or culpably careless. We think these issues should be tried in all cases of overlaying, and that mothers who overlay their infants through drunkenness should be treated as persons who commit murder through drunkenness. It is, or ought to be, criminal to kill a child, whether the murderer be conscious or unconscious of the act done, if the state of unconsciousness pleaded in excuse has been brought about by the wilful taking of an intoxicant.

VALUE OF AN INFECTIOUS DISEASES HOSPITAL.

IN a discussion by the Rochester Town Council concerning the infectious diseases hospital, it was stated that in every case of small-pox in the city the outbreak had been confined to the house in which it occurred, and with one exception to a single case, thus showing the importance of the hospital; for while at present there were only seven cases in the city, at Gillingham, where there was no hospital, it was believed there were nearly sixty cases. The Council thought the hospital should be free. It was added that it should be thoroughly understood that the better class of patients could always have their own private medical men to attend them in the hospital.

THE STOKE BRUERNE TRAGEDY.

MR. J. OSWALD LANE, M.B. Cantab., house-surgeon to the Northampton Infirmary, writes to say that the accused man, James Brooks, was admitted on March 4th with a compound depressed fracture of the vertex of the skull, caused by a self-inflicted gunshot wound; in addition, there was another lacerated wound of the right cheek, with contusion, &c., of the frontal region. The patient was trephined on the day of admission by Mr. R. A. Milligan, who removed the depressed bone and a number of shot which were found between the two tables of bone; he is progressing favourably up to to-day (March 12th), without any head symptoms. The case, which is of much interest, will on a future occasion be reported in full.

THE PATENT MEDICINES STAMP TAX.

DR. CAMERON has given notice that he will ask the Chancellor of the Exchequer whether he has yet received from the Board of Inland Revenue those reports on the Patent Medicines Stamp Tax which in the House of Commons on August 7th he undertook to "study with care," and if so, what action he proposes taking in the matter.

THE Alexander Prize and Gold Medal has been awarded to Surgeon John Martin, Medical Staff, for the best essay on Antiseptic Surgery and its application in Military Hospitals and on the Field. The subject for the next competition is on the Relations between the Food and Work of the British Soldier and their proper adjustment in Peace and War; on the occurrence of Scurvy among the Troops and its Prevention; and on the use of Preserved and Concentrated Foods, with Suggestions for Alterations or Improvements in the existing Rations and Times of Meals. Further particulars will be found in our advertising columns.

A SEVERE epidemic of measles is raging in Widnes, and at a meeting of the Local Board of Health on the 10th inst., it was resolved, by six votes to three, on the motion of Dr. O'Keefe, that the clerk be instructed to write to such manufacturers in Widnes as employed the 700 workmen who live in Runcorn and work in Widnes, requesting them to compel their men to live in Widnes or to cease employing them, so as to prevent a further spread of the disease.

DR. LOUIS ELSBERG, of New York city, Professor of Laryngology at Dartmouth Medical College, Professor of Laryngology and Rhinology at the New York Polyclinic, and Physician to the Throat Wards in Charity Hospital, New York, died at his residence in New York on the 19th ult., from pulmonary œdema, after ten days' illness. He was in the forty-eighth year of his age, having been born at Iserlohn in Prussia in 1837.

DR. CARL WEIGERT, formerly Professor Cohnheim's assistant at Leipsic, has been invited to succeed the late Professor Lucæ at the Senkenberg Anatomical Institute, Frankfort. He will also be prosector to the hospitals of that city. Professor Huber will succeed Professor Birch Hirschfeld, who leaves Dresden for Leipsic.

THE Medical Faculty of the Melbourne University has adopted and forwarded to the Council an elaborate report on the present state and requirements of the Medical School, a continuation and extension of a previous report sent in three years ago, in which considerable changes in the working of the institution are recommended.

MR. G. WATERS, L.R.C.S., has been appointed to act as Professor of Physiology in the Grant Medical College, vice Mr. N. Hojel, L.K.Q.C.P.I.; Mr. G. Manser, M.R.C.S., to act as Professor of Pathology in the same, vice Mr. Waters; and Mr. R. J. Baker, M.B., to act as Professor of Materia Medica, vice Mr. Manser.

NOTWITHSTANDING the comparative immunity from small-pox which Kensington has lately enjoyed, several isolated cases have occurred in different parts of the parish. The guardians, acting on Dr. Dudfield's advice, propose to adopt a house-to-house visitation, in order that vaccination may be properly carried out.

THE committee appointed last year to inquire into the origin of the noxious odours which, during the summer, made the House of Commons almost uninhabitable, will shortly resume their sittings. Important evidence has been prepared for submission to the committee.

SENOR MARIN BALDO has communicated to the Spanish Central Society of Architects a plan for constructing houses with roofs fastened to the uprights by means of movable joints in order to obviate danger to the inmates during earthquakes.

DR. R. P. SMITH, at present Resident Assistant Physician at St. Thomas's Hospital, was elected Junior Resident Medical Officer to Bethlem Hospital on the 9th inst.

MR. SHIRLEY MURPHY has tendered his resignation as medical officer of health to the parish of St. Pancras, an appointment which he has held for nearly seven years.

A FORMAL contradiction is given to the reports circulated of the reappearance of cholera at Marseilles.

IN addition to the *Calabria*, two other telegraph ships, the *Kangaroo* and the *International*, are to be sent to Suakim. The great advantage which this class of vessel possesses over others is the enormous tanks which can be made use of for the storage of fresh water.

WE learn that Dr. Simpson has been appointed Surgeon-General of Bombay, and that Dr. Payne has memorialised the Viceroy, but without success. Dr. Payne has, it appears, sent in his papers to retire from the service.

HEALTH OF THE NAVY.

THE annual report on the Health of the Navy for the year 1883, which has just been presented to Parliament, is of a very satisfactory character, the death-rate being the lowest recorded during the twenty-eight years in which these reports have been prepared. The average strength of the force afloat was 43,350; the cases of disease and injury which occurred in it were in the proportion of 1091, the deaths from all causes 5·88, the invaliding 38·75, and the mean daily sick 47·78 per 1000 of strength, the three first being considerably lower, and the last a mere fraction higher, than in the preceding year. Satisfactory, however, as this low ratio of mortality is, it is still more so if the deaths by accidents and injuries, which are always numerous in the navy, be deducted, the proportion from disease alone amounting only to 4·06 per 1000 of the whole force afloat at home and abroad. The cases ranged between 847 on the south-east coast of America, and 1624 on the China station; the deaths between 4·44 in the Irregular Force, and 9·83 on the China station; the invaliding between 15·51 on the south-east coast of America, and 61·09 from the Mediterranean; and the mean daily sick between 24·24 on the south-east coast of America, and 57·28 in China. The death-rate from disease, exclusive of injuries, was as low as ·94 on the Australian station, was 1·72 on the south-east coast of America, between 2 and 3 on the Pacific and African stations, and in the Irregular Force; 3·09 in the Mediterranean, 4·14 at home, and between 6 and 7 on the American and West Indian station, the China station, and the East Indies. The high rate of sickness on the China station was chiefly due to diseases of the respiratory and digestive systems, and to cases of phlegmon, abscess, and ulcer, and the excess of mortality was caused by cholera. Next to China, the East Indies furnished the highest ratio of admissions, the prevailing diseases being fevers, diseases of the digestive system, and those of the cellular and cutaneous systems; the African station also had a heavy sick list from the same causes. Diseases of the cellular tissue and cutaneous system are a source of considerable inefficiency throughout the service, the cases ranging from 210 per 1000 on the home to 434 per 1000 on the Australian station, and the average constantly non-effective from this cause amounting to 8·68 per 1000; they were the cause of only one death, which arose from "cellulitis of the neck, an abscess having burst into the trachea."

Of enteric fever 111 cases were admitted, and 19 died; of these, 60 cases and 11 deaths were on the home station. On the China station there was an outbreak of fever of the continued type, of which 307 cases were returned. They occurred chiefly among "the relief crews of the *Curaçoa* and *Victor Emanuel* while being conveyed from England to China in the *Thalia*, and appear to have been due to overcrowding, defective sanitation in the shape of foul bilges, and a want of due attention to cleanliness." The connexion between the disease and defective ventilation is supported by the fact that 217 men on the lower deck furnished 61 cases, while 215 on the main deck, which had a free supply of air, furnished only 21 cases. That the defective sanitation and overcrowding were the chief cause was further shown by the fact that on the return voyage, with a reduced number of men on board and after the ventilation had been improved at Hong Kong, there was no prevalence of disease in the ship. A considerable number of cases occurred among the men and boys after they were distributed among the ships on the station.

China was the only naval station on which any cases of cholera were recorded, and there 17 occurred, of which 9 proved fatal. Eight of them with 5 deaths took place on board the *Espoir* at the anchorage near Fowchoo, where cholera had been prevalent, and it appeared that the men who were attacked had partaken of lemonade made by the Chinamen, the water for which was drawn from a well in the most infected part of the village. Seven cases with 2 deaths occurred in the *Flying Fish*; the disease was contracted at Chefoo, where its presence was denied, and the crew were consequently granted general leave, but it was afterwards found that the statement was incorrect. A fatal case occurred in the *Kestrel* at Shanghai, and another, also fatal, in the *Foxhound* the day after leaving Tientsin. Syphilis was more prevalent on the home than on any of the foreign stations, as was also gonorrhœa, with the exception of China; the admissions for syphilis were upwards of 50 per cent. higher on the Home station than in 1882, a result which appears fairly attributable to the suspension of the working of the Contagious Diseases Acts. There was also a marked increase of cases in the Mediterranean, attributed, by the medical officers, to the bad sanitary condition in this respect of many of the places visited by the squadron in the summer cruise. Malta, Alexandria, and other Egyptian ports and Trieste were the places where the greatest amount of disease was contracted. It is worthy of note that during the year there were only 10 cases reported under the head of scurvy and purpura in the whole fleet.

In addition to the service afloat the report gives details of the health of the Royal Marines at head-quarters. Their average strength was 5450; the cases of disease and injury were in the ratio of 1148; the deaths of 5·68, the invaliding of 66·05, and the mean daily sick of 63·50 per 1000—all except the deaths considerably higher than among the force afloat on the Home station. But if the deaths by violence in each branch be deducted, the mortality of the marines will be found to be 5·32, against 4·14 in the service afloat. The admissions and deaths show a decrease, but the invaliding and mean sick an increase upon the results of the preceding year.

UNIVERSITY DEGREES FOR LONDON MEDICAL STUDENTS.

A MEETING of the Metropolitan Counties Branch of the British Medical Association was held on March 6th at the Royal School of Mines, Jermyn-street, Mr. Macnamara, President of the Branch, in the chair.

Mr. MACNAMARA opened the proceedings by narrating some of the circumstances which had led the Council of the Branch to draw up a report on the subject of University Degrees for London Medical Students. In the compilation of the statistics, and in the construction of the report, which had been widely circulated, he said the Council wished to acknowledge the most valuable services of Dr. Gilbart Smith. He briefly summarised the features of the report, and then called upon Dr. Bristowe to move the resolution, of which the following is a copy:—"That the report of the Council of the Branch on University Degrees for London Medical Students be adopted; and that the Council be directed to petition the Senate of the University of London to receive a deputation of members of the branch in support of the objects aimed at in the report."

Dr. BRISTOWE said that the statistics contained in the report proved beyond doubt that the University of London was not fulfilling the functions which its well-wishers hoped that it would do. The University of London is less the university for the metropolitan schools than are the Scotch and Irish universities. Of the 16,192 practitioners practising in England, only 5219, or 32·2 per cent., are graduates. Of the 2206 medical men practising in Scotland, 1557, or 70·6 per cent., possess university degrees; and of the 24·30 men engaged in medical practice in Ireland, 925, or 38·0 per cent., are graduates of a university. A difference still more striking is observed, however, when inquiry is made into the sources whence the different degrees are obtained in the three kingdoms; for it will be seen that of the 5219 men possessing degrees in England, but 1076, or 20·6 per cent., derive the title from an English university, while as many as 62·7 per cent. are indebted for their degrees to the Scotch universities. Of the 1557 who possess degrees in Scotland, 1537, or 98·7 per cent., have acquired their titles

from a native source; and in Ireland, of the 925 men who hold degrees, 672, or 72·6 per cent., possess Irish degrees, and 243, or 26·3 per cent., are graduates of Scotch universities. The same relative paucity of English degrees is observable among medical officers in the public services and the practitioners resident abroad. Looking at this state of affairs, Dr. Bristowe thought that matters could be best mended if the London University were made to meet the requirements of London medical students. He suggested that the matriculation examination might remain as it was, but that the Preliminary Scientific Examination should undergo a radical change, even if it be not abolished altogether. In his opinion none of the subjects in which the candidates were examined were of any benefit to practical medical men. He did not think there need be any modification in the final examinations for the London University medical degrees.

Mr. RIVINGTON seconded this resolution.

Mr. S. J. HUTCHINSON proposed an amendment, which was seconded by Mr. BRINDLEY JAMES.

Dr. BRIDGEWATER also spoke on the resolution.

Another amendment, proposing to leave out of the resolution all terms relating to the University of London, was proposed by Dr. SANSOM and seconded by Dr. RAYNER.

Both amendments were lost.

Mr. VICTOR HORSLEY inquired whether the view that the subjects of the preliminary scientific examination were of no value to medical men would form part of the petition to be presented to the Senate of the University of London. He could not agree that the subjects were not important for the medical man.

Mr. MACNAMARA replied that that was merely an individual opinion, and was not embodied in the report.

Mr. NELSON HARDY spoke on Dr. Sansom's amendment, and maintained that the resolution would lose all its force if this proposal were adopted.

Mr. SMITH TURNER proposed and Dr. LAUDER BRUNTON seconded that the names of the hospitals which appeared on p. 17 of the Report of the Council of the Branch be expunged therefrom. This amendment was carried unanimously.

The second resolution was proposed by Dr. ROBERT BARNES. It is as follows:—"That failing to obtain concessions from the Senate of the University of London, the Council be empowered to take, in conjunction with the Royal College of Physicians of London and the Royal College of Surgeons of England, such steps as they may deem necessary to facilitate the obtaining of degrees in medicine by London medical students." Dr. Barnes said that the University of London was a failure, and was far behind its own work, although it had given a fresh impetus to the study and progress of medicine when the university was first established. He did not believe that the suggestion of Dr. Sansom that a new degree of M.C.D., entitling the holder to consider himself a doctor in medicine and surgery, was a good one. For, in the first place, medicine was one, and undivided; and, secondly, the public would never be got to believe that such a degree implied the possession of as much knowledge as the possession of the ordinary M.D. degree. After all, the public must be consulted in a large measure.

Dr. HICKMAN seconded the resolution, which was put to the meeting and carried unanimously.

A vote of thanks to Dr. Gilbart Smith for his services in drawing up the report brought the meeting to a close.

VACCINATION GRANTS.—Mr. R. Istance, of Risca (sixth time), and Dr. James Lily, of Brentford, have received the Government grant for successful vaccination.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Bristol Urban District.—Mr. Davies records a slight increase in the mortality for the city of Bristol, and he attributes it in the main to the amount of diarrhœal disease consequent upon the exceptional heat of the past summer. The rate was, however, not very high for such a city as Bristol, reaching as it did to only 18·7 per 1000. The only two cases of small-pox which occurred were at once isolated, and it is estimated that a considerable extension of disease was thus prevented. As to scarlet fever, Mr. Davies lays it down as his rule to refuse to remove patients unless he is allowed to remove all who are affected with the disease in the house; in short, unless the points of infection in the city are diminished by the removal. No one will probably desire to disagree with this view. The object of a medical officer of health in securing isolation is the prevention of disease rather than the welfare of the individual patient. But the isolation of scarlet fever has always been at a low ebb in Bristol, and the fear as to "the formation of a concentrated centre of infection" is evidently at the bottom of it. The matter is one of such importance that we could wish to see Mr. Davies offering some proof of his belief as to this, in addition to his constant reiteration of it. The London Fever Hospital has contained a larger aggregation of scarlet fever patients over a long series of years than any other hospital in England, and the proof is overwhelming that, though situated in a populous portion of the metropolis, no extension of the disease has taken place. In 1884 only two patients were admitted to the Bristol Fever Hospital, whereas of scarlet fever alone there were thirty-seven deaths. Speaking specially of diarrhœa, Mr. Davies points out that this disease was debited with 132 deaths, against 83 during the previous year, and he regards the excess as due to three factors—namely, the summer season, the warm dry weather, and artificial feeding. He is inclined to think that the first two favour the development of bacteria in cow's milk after being exposed in damp mouldy cellars or musty cupboards; and as regards the latter, he adverts in one portion of his report to the increasing employment of women as breadwinners instead of men. The zymotic death-rate as a whole was 1·8 per 1000, being 0·7 in excess of that for the previous year; but even this is by no means an exceptional rate for such a population as that under consideration.

Bristol Port District.—It appears that as the result of Dr. Blaxall's official visit to this port a methodical inspection of shipping has now been commenced, and it is reported that much work in cleansing has been effected. Mr. Davies is also of opinion that the inspection, as required by the Local Government Board, will doubtless add materially to the comfort of the crews. Four cases of enteric fever were discovered. A small hospital is evidently needed for the special purposes of the port, and the matter is receiving the attention of a committee.

St. Marylebone.—Some action is again being taken with regard to the dwellings of the poor under Torrens' Act. Mr. Wynter Blyth has reported adversely in the case of houses in Conway-court and Grafton-court, and in each case the subsequent report of the surveyor is to the effect that since no structural alteration or repair will render these houses fit for human habitation, he therefore recommends that they should be demolished. The regulations as to houses let in lodgings have now received the sanction of the Local Government Board, and they will at once be put into operation in certain localities where they are most needed.

Aston Rural District.—Dr. Bostock Hill presents a report as to this district. In the main it deals with the nine months during which he has held office. For the whole of 1884 the birth- and death-rates were 26·9 and 14·5 per 1000 respectively, and the zymotic rate was 1·2. This speaks satisfactorily for the district, and it is evident from the record of work that efforts are made by tent hospital isolation and otherwise to control the spread of infectious fevers. Numerous and systematic inspections of the district have been made; bakehouses are looked after; cleansing and disinfection, both of infected premises and infected clothing, have been carried out; and the authority have certain

arrangements with the Aston Local Board of Health whereby they will soon be provided with permanent means of isolation in the excellent hospital which the latter authority are now erecting. One sentence of grave importance is included in the report. It is to the effect that at the present time numerous houses are directly or indirectly draining into the Brook, from which the Birmingham Corporation draw part of their water-supply, and since one division of the rural district receives this water-supply, this district is in point of fact not only injuring its great neighbour, but polluting its own drinking water. Such a state of affairs should, in view of cholera prospects, be dealt with as an urgent matter.

Montrose Sanitary District.—Montrose, with a population of 16,476, had a death-rate of 24·4 per 1000 in 1884; and making the necessary deductions for the asylum, &c., it still stood as high as 22 per 1000. It is explained that during the year there was a higher mortality than usual amongst infants, and also from non-epidemic diseases. The report, however, contains no information as to the sanitary state of the town, and hence we are unable to express any opinion as to the cause of a mortality which is certainly excessive.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

In twenty-eight of the largest English towns 5826 births and 3515 deaths were registered during the week ending the 7th inst. The births exceeded by 12, while the deaths were 112 below, the average weekly numbers during 1884. The annual death-rate in these towns, which had been 20·5 and 21·4 per 1000 in the preceding two weeks, declined again to 20·6 last week. During the first nine weeks of the current quarter the death-rate in these towns averaged 22·5 per 1000, against 24·7 in the corresponding periods of the nine years 1876-84. The lowest death-rates in these towns last week were 11·8 in Brighton, 14·6 in Hull, 15·2 in Wolverhampton, and 15·8 in Plymouth. The rates in the other towns ranged upwards to 29·1 in Preston, 29·3 in Newcastle-upon-Tyne, 37·6 in Cardiff, and 42·1 in Sunderland. The deaths referred to the principal zymotic diseases in the twenty-eight towns, which had been 384 and 377 in the previous two weeks, rose to 395 last week; they included 133 from measles, 112 from whooping-cough, 42 from scarlet fever, 33 from "fever" (principally enteric), 28 from diarrhœa, 24 from diphtheria, and 23 from small-pox. No death from any of these zymotic diseases was recorded last week in Derby, whereas they caused the highest death-rates in Bristol, Cardiff, and Sunderland. The highest death-rates from measles occurred in Cardiff and Sunderland; from whooping-cough in Bristol and Cardiff; from scarlet fever in Wolverhampton and Preston; and from "fever" in Newcastle-upon-Tyne, Blackburn, and Norwich. The 24 deaths from diphtheria in the twenty-eight towns included 15 in London and 2 in Newcastle-upon-Tyne. Small-pox caused 37 deaths in London and its outer ring of suburban districts, 2 in Liverpool, 2 in Manchester, 1 in Birmingham, 1 in Birkenhead, and 1 in Sunderland. The number of small-pox patients in the metropolitan asylum hospitals situated in and around London, which had been 1223, 1141, and 1103 on the preceding three Saturdays, further declined to 988 at the end of last week; the admissions, which had been 255, 163, and 170 in the previous three weeks, declined to 94 last week. The Highgate Small-pox Hospital contained 95 patients on Saturday last, 19 cases having been admitted during the week. The deaths referred to diseases of the respiratory organs in London, which had been 343 and 384 in the preceding two weeks, were 374 last week, and 106 below the corrected weekly average. The causes of 93, or 2·6 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Brighton, Blackburn, Wolverhampton, and Plymouth. The largest proportions of uncertified deaths were registered in Oldham, Salford, and Sheffield.

HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 23·1 and 24·6 per 1000 in the preceding two weeks, declined to 22·8 in the week ending the 7th inst., this rate, however, exceeded by 2·2 the mean rate during the same week in the twenty-eight large English towns. The rates in the Scotch towns last week ranged from 13·3 and 15·6 in Perth and Aberdeen, to 21·2 in Greenock and 29·0 in Glasgow. The 557 deaths in the eight towns included 20 which were referred to measles, 19 to whooping-cough, 12 to scarlet fever, 9 to diarrhœa, 6 to diphtheria, 5 to "fever" (typhus, enteric, or simple), and not one to small-pox; in all, only 71 deaths resulted from these principal zymotic diseases, against 95, 81, and 82 in the preceding three weeks. These 71 deaths were fewer than in any previous week of this year, and were equal to an annual rate of 2·9 per 1000, which exceeded the mean rate from the same diseases in the twenty-eight English towns by 0·6. The fatal cases of whooping-cough, which had been 30 and 31 in the previous two weeks, declined to 19 last week, a lower number than in any week since the end of November; they included 9 in Glasgow and 4 in Dundee. The 20 deaths from measles showed an increase of 5 upon the number in the previous week; 17 occurred in Glasgow and 3 in Dundee. Eleven of the 12 deaths from scarlet fever and 4 of the 5 from "fever" were returned in Glasgow; the mortality from these causes showed a decline. The 6 deaths from diphtheria included 3 in Edinburgh. The deaths referred to acute diseases of the respiratory organs in the eight towns, which had declined in the preceding five weeks from 214 to 125, further fell last week to 119, and were one below the number returned in the corresponding week of last year. The causes of 65, or nearly 12 per cent., of the deaths registered last week in the eight Scotch towns were not certified.

HEALTH OF DUBLIN.

The rate of mortality in Dublin, which in the preceding four weeks had declined from 36·2 to 30·3 per 1000, rose again to 32·7 in the week ending the 7th inst. During the first nine weeks of the current quarter the death-rate in the city averaged no less than 32·7 per 1000, the mean rate during the same period not exceeding 21·5 in London and 20·4 in Edinburgh. The 221 deaths in Dublin last week showed an increase of 16 upon the number returned in the previous week, and included 27 which were referred to the principal zymotic diseases, exceeding the number in any previous week of this year. Of these 27 deaths, 10 resulted from measles, 6 from "fever" (typhus, enteric, or simple), 4 from scarlet fever, 4 from whooping-cough, 3 from diarrhœa, and not one either from small-pox or diphtheria. These 27 deaths were equal to an annual rate of 4·0 per 1000, the rate from the same diseases not exceeding 1·9 in London and 1·2 in Edinburgh. The 10 fatal cases of measles in Dublin, showed an increase of 2 upon the number in the previous week; and the 6 deaths from "fever" also showed a considerable increase, as but 1 death from this cause had been returned in each of the previous two weeks. The fatal cases of scarlet fever showed a decline, while those of whooping-cough were more numerous. Three inquest cases and 1 death from violence were registered; and 69, or nearly a third, of the deaths in the city were recorded in public institutions. The deaths of elderly persons showed a considerable decline from recent weekly numbers. The causes of 29, or more than 13 per cent., of the deaths registered in the city last week were not certified.

THE SERVICES.

THE EGYPTIAN EXPEDITION.

To the list of Indian medical officers proceeding on active service with the Indian Contingent for the Soudan, as published in our issue of last week, we have to add the names of the following:—Brigade Surgeon Thornton (as Principal Medical Officer); Surgeon-Major R. Boustead, Officiating Medical Officer 21st Bombay Infantry; and Surgeon A. C. Thompson, Medical Officer, Asirgarh.

We regret to announce the death, from enteric fever, of Surgeon Turner, of the British Medical Service, which took place at Korti, in the Soudan, on Friday, the 6th instant.

The following are among the officers belonging to the New South Wales Contingent who have gone to Suakim:—Surgeons Williams, Glanville, and Trowfoot.

The Council of the National Aid Society has sanctioned the extension in the Upper Nile of the system, already inaugurated, for evacuating the sick and wounded towards Cairo,

and has empowered Major Young to order the construction of another steam launch in every respect suitable for the object to be attained; this second launch to be employed at a higher level on the Nile than that where the *Queen Victoria* is operating. Consequent upon the extension of military operations and the departure of a military force to Suakim, the Council has appointed, as second Commissioner to the Forces under Lord Wolseley, Mr. V. B. Kennett-Barrington. The sphere of operations over which Major Young will preside will include the valley of the Nile, Cairo, and Suez. Mr. Kennett-Barrington will take charge of that portion of the Expedition which will have its headquarters at Suakim, and will include all operations extending from Suakim to Berber, and the establishing of depôts and temporary hospitals for the relief of sick and wounded as they are evacuated towards the port of embarkation; also the evacuation of the sick by means of the sea route to Suez. An offer has been made by Sir Allen Young to place his yacht *Stella* at the service of the Society for the above purpose. This offer has been accepted, and Sir Allen Young has been appointed their Commissioner afloat, attached to the Suakim ambulance.

The work of the Red Cross Society will, it is stated, occupy an important place in the Antwerp Exhibition. The international exhibition of the hospital institutions of all countries which have agreed to the Convention of Geneva will be completed in September by a competition in the construction of field hospitals, when the prize of 6000 francs, offered by the Empress of Germany, will be awarded. Everything will be ready for the opening on May 2nd.

Surgeon-General C. D. Madden, of the Army Medical Staff, has been selected for the important position of Principal Medical Officer to the troops in India, vice Surgeon-General Sir Anthony Home.

INDIA OFFICE.—The Queen has approved of the following promotions among the officers of the Staff Corps and Indian Military Services made by the Governments in India:—Surgeon-Major Charles Edwin Raddock, of the Bengal Medical Establishment, to be Brigade Surgeon; Surgeon Kenneth Mackenzie Downie, M.D., of the Bengal Medical Establishment, to be Surgeon-Major.

The following Indian medical officers have retired from the Service:—Deputy Surgeon-General A. J. Payne, M.D. (Bengal); Deputy Surgeon-General Colvin Smith, M.D., C.B. (Madras); Brigade Surgeon J. Jones, Brigade Surgeon S. M. Shircore, and Surgeon-Major T. S. Veale, M.D. (all Bengal).

ADMIRALTY.—The following appointments have been made:—Henry D. Stanistreet, Fleet Surgeon, to the *Jumna*; George W. Lowe, Surgeon, to the *Mariner*.

MILITIA MEDICAL STAFF.—Surgeon-Major Charles Harwood, 5th Battalion, the Sherwood Foresters (Derbyshire Regiment) resigns his commission, also is permitted to retain his rank, and to wear the prescribed uniform on his retirement.

RIFLE VOLUNTEERS.—2nd Hampshire: Surgeon Theophilus William Trend, M.D., is granted the honorary rank of Surgeon-Major.—16th Lancashire (3rd Manchester): William Henry Brownbill Crockwell, Gent., to be Acting Surgeon.—1st London (the City of London Rifle Volunteer Brigade): William Adams Duncan, Gent., M.D., to be Acting Surgeon.—12th Middlesex (Civil Service), Surgeon Arthur Trehern Norton is granted the honorary rank of Surgeon-Major.—6th (West) Suffolk: Acting Surgeon Charles Watts Wistler resigns his appointment.—2nd Sussex: Surgeon Charles Francis Lewis is granted the honorary rank of Surgeon-Major.—2nd Volunteer Battalion, the Worcestershire Regiment: Surgeon Archibald Weir, M.D., resigns his commission, also is granted the honorary rank of Surgeon-Major, and is permitted to continue to wear the uniform of the battalion on his retirement.

A CONFERENCE of the examining staff of the St. John Ambulance Association was held recently, Dr. Sieveking in the chair, for the further consideration of a report on the method of conducting examinations. A lengthy discussion took place, among the speakers being Drs, J. C. Steel, J. P. Wilton, and Crespi, Mr. F. B. Baker (Grenadier Guards), Mr. S. Benton, Fleet-Surgeon H. C. Woods, R.N., Drs. Roberts, Law, Collingridge, and H. Percy Potter, and Deputy Inspector-General M. Coates, R.N.

Correspondence.

"Audi alteram partem."

VACCINATION.

To the Editor of THE LANCET.

SIR,—I have just received a copy of THE LANCET of Feb. 28th, which probably you have been kind enough to send to me. By punctuating the sentence, "One child had erysipelas; one domestic, scarlatina," you will the better understand it, and be spared any apprehension of the advent of a "new disease." Since the interview with the deputation of my constituents, which has engaged your attention, I have from time to time read one or two interesting works on the vexed question of vaccination. Amongst others, I have met with a small thin quarto volume published by Jenner at the end of the last century. When you express the opinion that you and I are not likely by any spread of intelligence to be liberated from the duty of "praising God for men like Edward Jenner, as the very greatest benefactors of their race," you echo my own hitherto passively accepted opinion. What I now want to know is, for which of the three several propositions in Jenner's account of his discovery we are to hold ourselves indebted to him? 1. His decision that the true protective cow-pox was that which was produced in the cow by transmission from the diseased heel of a horse. 2. That the healthy subject, being once thoroughly infected by inoculation with this particular cow-pox, was permanently protected against small-pox. 3. That inoculation with cow-pox matter being thus protective, inoculation with small-pox matter itself, which had been the orthodox practice of the medical faculty for a generation, ought to be discarded. As the earliest result of my consideration of Jenner's claims on our gratitude, I am inclined to rank the third proposition very highly. To have provided a less offensive and dangerous inoculation, when inoculation was believed to be absolutely essential against the virulence of small-pox, was an appreciable boon. The second proposition of Jenner, that once well vaccinated was to be always protected, I am spared the duty of thanking him for, the medical profession having declared it to have been an erroneous supposition. Whether Jenner adhered to his discriminating theory of the difference in efficacy between true and "spurious" cow-pox—i.e., between cow-pox traced to communication with the diseased heel of a horse and cow-pox not so traced—I am at present uncertain. Perhaps you can inform me.

I am, Sir, yours very truly,

House of Commons Library, March 6th, 1885. ROBT. LEAKE.

*** We refer Mr. Leake to a leader on vaccination in another page of our impression of to-day.—ED. L.

SEASIDE SANITATION.

To the Editor of THE LANCET.

SIR,—Spring is rapidly approaching, when persons will be flocking to the seaside to recruit themselves with fresh sea air after the long, weary winter, and in the hope of laying in a fresh stock of health for the future.

It is proverbially ungracious to spoil a pretty picture, but in the interests of all seaside frequenters I would wish to give a word of warning. Thanks to the information frequently afforded in the pages of THE LANCET, and in Mr. Teale's admirable work "Dangers to Health," we are now well acquainted with all the details of what may be called "sanitary plumbing." Slowly but surely our homes are being made healthier, all sanitary defects being removed, and replaced with the latest improvements. Shall we find all these at the seaside? If so, well and good; if not, those who are not acclimatised to close rooms, impure water, and sewer gas will, I fear, pay the penalty in the shape of sore-throat, diarrhœa, or even an attack of typhoid fever.

One would expect that soil-pipe ventilating shafts and "wash-out" closet basins would now be regarded as necessities in every house where lodgers are taken in. Unless, however, my experience is very exceptional, they are only to be found in new or first-class hotels, and very rarely in lodgings. The average watercloset in a seaside

hotel or lodging-house is still frequently a very small, ill-ventilated place, not unfrequently with only a borrowed light, having, what is now justly regarded as an insanitary abomination, the old pan closet, plastered thick with fæcal matter, with most inefficient water-supply, and giving off an odour which is simply poisonous.

I should like to ask medical officers of health whether it is the duty of lodgers to report to them such defects as I have described, and if they have power to enforce the remedy? In these days of actions against medical practitioners it might be dangerous to suggest a "black list" of insanitary lodgings. But our brethren in seaside towns might ably assist the cause of sanitation by urging it upon such of their patients as let lodgings, and by only recommending to visitors such as are absolutely safe. Until some such guarantee can be had, I fear that we shall continue to hear of mysterious illnesses occurring during, or shortly after, a seaside visit, while many besides myself will contemplate a visit to the seaside with great anxiety.

I am, Sir, yours truly,

March 10th, 1885. A PROVINCIAL SURGEON.

SUICIDE.

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 21st, you were kind enough to announce that I had delivered a lecture on "Suicide, Its Causes, and the Best Means of Prevention," at a meeting held in the Medical Society's Rooms. As I am still collecting statistics on suicides, attempted and accomplished, I should be glad if any of your readers will favour me with any information obtained by themselves of the "Relative Proportion of Attempted and Complete Suicides."

I am, Sir, yours truly,

WYNNE WESTCOTT, M.B.,
Deputy Coroner for Central Middlesex.

Torriano-avenue, Camden-road, N.W.

BIRMINGHAM.

(From our own Correspondent.)

WOMEN'S HOSPITAL.

THE annual meeting of this Charity was held on the 11th inst., when the report of the Managing Committee was presented; 294 cases had been treated as in-patients during the year, and 239 operations performed. The committee expressed their regret that the results obtained at the in-patient department did not compare favourably with those of the preceding year, 12 deaths having occurred among the 133 patients upon whom major operations had been performed. After declaring that the hospital arrangements were in every way satisfactory, and that these did not justify them in explaining the causes of the increased mortality, they say that they are forced to the conclusion that any variations in the results must be due to causes which are personal to the operating surgeons. There are but two of these, and it must be annoying to them to hear the chairman of the committee propound his opinion that, just as the greater success was due to greater skill, less favourable results were due to less skill. Some exception was subsequently taken to the wording of the report as it thus stood, and it was eventually resolved to alter the construction of the sentence, that it might read, "must be *mainly* due to causes which are personal to the operating surgeons," a reflection which is indicative of the authority under which the managing body hold their rule. An additional instance of the arbitrary nature of the tenure in which the professional staff hold office was shown in the adoption of the following law: "It shall not be competent for any member of the acting staff to accept or hold any acting medical appointment upon the staff of any other institution without the consent, in writing, of the Committee of Management." Truly, we live in an enlightened and liberal town, whose motto is "Forward."

HALFPENNY DINNERS.

A short time since attention was drawn to the working of the penny dinner movement for school-children, and it was shown that a palatable and nutritious meal could be provided for that sum with a margin of profit after all expenses had been included. A step further has been taken in this praiseworthy direction, and an experiment is being conducted by which the very poorest children may be provided with a good meal for the modest amount of a halfpenny. As many as 303 children were fed on the first day, the number going up afterwards to 566. A choice within a certain limit is given, and care is taken to make the food agreeable and wholesome. The first course consists of a rich stew or bacon sandwiches, the second of bread and jam or bread and cheese. That the children find the dinners ample to satisfy their hunger is shown by the fact of their continued attendance and the little waste made. From the calculations it is demonstrated that, with the cook's wages, cost of gas, and implements excepted, there is no loss, and that they can be made self-supporting.

A WISE VERDICT.

At an inquest recently held in an adjoining town, it was shown that a woman, aged thirty, found in a canal, died from the effects of an attempt to commit suicide. The jury returned a verdict of "Death from shock to the system," a conclusion which affords considerable range to human probabilities in the form of death, and is remarkable for its vagueness. We are reminded of the ingenuous reply of the man who, when asked what his father died from, said that his death was due to a sudden fall from a scaffold early one morning while engaged in conversation with the city chaplain!

Birmingham, March 11th, 1885.

GLASGOW.

(From our own Correspondent.)

THE UNIVERSITY.

THE Lord Rector of the University, Dr. Lushington, gives his inaugural address to the students on March 26th, when he will doubtless meet with an enthusiastic reception. The Chair of Botany in the University has become vacant through the appointment of Dr. Bayley Balfour as Sherardian Professor of Botany in the University of Oxford. There are already at least three candidates in the field.

EXTRA HOSPITAL ACCOMMODATION.

The Public Works Loan Commissioners have granted the application of the Glasgow Local Authority for a loan of £28,000 for the construction of additional pavilions to the Hospital for the Treatment of Infectious Diseases at Belvidere.

MORTALITY OF GLASGOW AND ITS SUBURBS.

There has been under discussion lately a proposal that there should be prepared monthly a statement of the total death-rate in the city and its suburbs, so that a fair comparison might be made with the other large towns in the kingdom. It is very desirable that this should be done, as at present our vital statistics are very defective and misleading, the Glasgow registration district including only the central portion of a community, from which the circumferential part, divided from it in most cases only by a boundary line, is excluded.

EXPERIMENTS ON THE EFFECTS OF LOW TEMPERATURES.

At a meeting of the Glasgow Philosophical Society, Prof. McKendrick and Mr. J. J. Coleman gave an account of some recent experiments on the effects of low temperatures on the putrefactive process and on vital phenomena. They found that the continued exposure of putrescible fluids to a temperature of 120° below zero did not prevent putrefaction, showing that the micro-organisms causing putrefaction are not killed even by this extreme cold, a temperature probably lower than any prevailing in the Polar regions, so that micro-organisms may exist even there. They hoped to continue their experiments with an atmosphere at a temperature of 150° below zero.

CASES OF LEPROSY IN GLASGOW.

During the last few months practitioners in Glasgow have had an opportunity of studying two very typical cases of leprosy, in which the signs of all the varieties of the disease were manifest—the tubercular, macular, anæsthetic, and ulcerating forms. At one of the Societies also the leprosy bacillus has been exhibited.

GLASGOW PUBLIC DISPENSARY.

The annual meeting of this institution was held a few days ago, when an interesting report was presented. In the notes regarding cases of ear and skin diseases, it was stated that two patients had been treated for acute ear affection caused by a "box on the ear" from school teachers—a form of punishment which is very reprehensible. In giving the statistics of some of the departments, a distinction is made between the number of individual patients seen and the number of consultations—a distinction which may be commended to the other medical charities of the city, where every patient, whether he be a new comer or have been seen before, has his name entered anew, with the object apparently of swelling their statistics, It is stated also in this report that an electric light apparatus has been set up in the dispensary, the dynamo being worked by a small water-wheel, a "Hercules" turbine; the leading wires pass directly from the dynamo to the electric lamps in the consulting-room, where the light is used in physical examination.

Glasgow, March 11th.

PARIS.

(From our Paris Correspondent.)

THE SURGICAL TREATMENT OF VARICOCELE.

AT a recent meeting of the Academy of Medicine, Dr. Horteloup, Surgeon of the Hôpital du Midi, read a note on the Surgical Treatment of Varicocele, wherein he proposed a radical cure for that troublesome affection. Dr. Horteloup stated that, although he was aware that after the age of thirty the malady gradually disappeared spontaneously, yet he thought something should be done to render life supportable, even if the malady could not be cured before that age. This is all the more desirable in the cases of young men who present themselves for enlistment in the army, several of whom are annually rejected on account of the infirmity. Various methods of cure have been employed by surgeons, but they have proved merely palliative, and very frequently patients were sent away with only a suspensory bandage, which they had to wear for an indefinite time. In other cases, when operative measures were adopted, several fatal accidents have occurred, which caused some repugnance to surgical interference. Dr. Horteloup, however, considers that, since the application of the antiseptic treatment of wounds, &c., the opinions of surgeons have been considerably modified as to the result of surgical operations, and he did not see why a patient suffering from the affection in question should be denied the benefits of an operation. That proposed by Dr. Horteloup consists simply in cutting out a rather large portion of the scrotum on each side, thus reducing it to a size that would enable it to form sufficient support to the testicle and the spermatic cord. Dr. Horteloup has performed this operation eighteen times within the last two years, and he found that, the size of the scrotum having been reduced, the suspensory bandage could be advantageously dispensed with.

THE DIAGNOSIS OF SUBMERSION DURING LIFE OR AFTER DEATH.

Struck with the divergences of opinion among authors as to the diagnosis of submersion having taken place during life or after death, Dr. Bougier made the subject an object of study, and during a whole year he had performed several experiments and autopsies at the Morgue, of which he gave an account in his thesis for the doctorate, which he obtained about a month ago. The author's conclusions are as follows: 1. The exterior aspect of the body is about the same in both cases—that is, when the body has been submerged before or after death; the appearance of moss on the body would be of some diagnostic value. 2. Water and foreign bodies penetrate into the air passages and in the bronchial tubes of those submerged before, as well as of those immerged, after death; but in the latter the foreign bodies do not go beyond the fifth or sixth divisions of the bronchial tubes, and the liquid is arrested at the bronchi of medium size by the column of compressed air; whereas, in the submerged during life, it penetrates down to the small bronchial tubes. 3. The epiglottis is vertical in the submerged; it is only half open in the corpses immerged. 4. Water penetrates in a pretty large quantity to the stomach of the former, but never to that of the latter; and in making a comparative analysis of the liquid found in the bronchial tubes, one might arrive at a certain diagnosis. 5. The same is the case with the middle ear. 6. The characteristic moss is found only in the submerged. 7. If the fluidity of the blood exists in certain cases of poisoning by opium, it is easy by the aid of the spectroscope, and by analysis, to form the diagnosis. 8. In putrefied corpses, all the signs have nearly disappeared, and the medical jurist can only draw conclusions by presumptions.

RETIREMENT OF HOSPITAL PHYSICIANS.

Dr. Hérard, physician to the Hôtel Dieu, and Dr. Bernutz, physician to the Charité Hospital, having attained the limit of age for hospital physicians, have been placed on the retired list, and the title of honorary hospital physicians has been conferred on them..

FEELING AGAINST FOREIGN MEDICAL STUDENTS.

The animosity that has long since been brooding between the French and Germans appears to have extended to all foreigners, especially the English and Americans, and the spirit of exclusiveness on the part of the French even manifests itself in the medical profession. The Paris Municipal Council, however, decided at its last meeting, by forty-one votes against two, that foreign medical students who have taken their inscriptions at the Faculty of Medicine will continue to be admitted as heretofore, as internes or externes of hospitals, but for the functions of hospital physician or surgeon, or for the prosectorate, the candidates will have to be naturalised.

The Société Française of Otology and Laryngology will hold its general meeting at Paris on the 2nd, 3rd, and 4th of April, 1885, at 8 o'clock in the evening, at the mairie of the 1st arrondissement.

Paris, March 11th.

THE ROYAL COLLEGE OF SURGEONS.

AT an ordinary meeting of the Council of the Royal College of Surgeons of England held on the 12th instant, the report of the Committee of Management of the Royal College of Physicians and the Royal College of Surgeons on the letter of December 1st last from the President of the General Medical Council was approved, adopted, and entered on the minutes.

It was decided to elect an additional Examiner in Elementary Physiology; this was referred to the Nomination Committee for report. A letter was read from Dr. Peter Redfern, of Belfast, asking for recognition of the certificates of vaccination granted in Belfast. To this the Council replied, that the College was pledged to the Local Government Board of England to receive those certificates only which are recognised by it; and if any alteration be made, it must be through the Local Government Board.

A vote of thanks was unanimously given to Professor John Marshall for the Hunterian Oration, which he was requested to publish.

MEDICAL NOTES IN PARLIAMENT.

Criminal Lunatics.

IN the House of Lords, on the 10th inst., the Earl of Milltown moved for a copy of the warrant under which Frederick Marshall, who was committed for trial at the Central Criminal Court charged with the wilful murder of his sweetheart at Woolwich, and against whom a true bill was found by the grand jury, was removed from the jurisdiction of the court before his trial, and committed to Broadmoor Asylum as a criminal lunatic by a warrant signed by the Secretary of State. The noble lord objected strongly to the law by which a presumably innocent person could be sent without trial to pass the rest of his life among criminal lunatics; and he argued that in the hands of a weak Home Secretary, and in the case of a wealthy or influential person charged with the murder, the power might become very dangerous. After some discussion, the Lord Chancellor stated that he considered this person was a prisoner because he was detained under the authority of the

law in prison. Nor did he see anything unreasonable in taking such a person to a criminal lunatic asylum; because, until a recent alteration was made in the law, it was the constant practice to detain in these criminal lunatic asylums, under the authority of the Crown, persons not convicted, but acquitted on the ground of insanity. The motion was negatived.

The Sale of Poisons.

In fulfilment of a pledge given by the Government last year, a Bill has been presented in the House of Peers for regulating the sale of poisons. One of its main objects is to prevent the unrestricted sale of such patent medicines as are poisonous.

Over-pressure in Board Schools.

In the House of Commons, on the 6th inst., Mr. Mundella, in reply to Mr. Leighton, stated that the London School Board is at present conducting a searching inquiry into the allegations made in Dr. Crichton Browne's report, all of which relate to London schools. The Education Department has taken no steps in consequence of that report, inasmuch as long before anything was heard of it, provisions were introduced into the Code which, by general testimony, have done all that the central government can do to prevent over-pressure.

The Metropolitan Asylums Board.

On Thursday, Mr. G. Russell, replying to Lord G. Hamilton and Mr. Stuart, said the Local Government Board had received a copy of the report of the Committee of Managers of the Metropolitan Asylums District as to their investigation into the expenditure on the Eastern Hospital, and of the notes of the evidence. The investigation extended over ten days, and the evidence, which is very voluminous, was only received by the Board three days ago. The subject is now under consideration by the Board, and no decision as to the course to be taken had as yet been arrived at. The accounts of the Managers of the Metropolitan Asylums District show that, comparing the year ended Lady Day, 1884, with the year ended on the same day in 1880, the expenditure, excluding expenditure out of loans, has increased by £187,000. Without going into the details of the expenditure, it may be observed that, since 1880, an asylum for 900 imbecile patients has been erected at Darenth, three hospital ships for small-pox patients have been provided, the North-Western Hospital has been opened, and wharves and ambulance stations have been established. There has also been a large outlay on alterations and additions at the Small-pox and Fever Hospitals since the date of the report of the Royal Commission, with the view of diminishing any risk of spread of disease from the hospitals, and also a considerable increase in the payments in respect of principal and interest of loans.

Dr. Hall and Mr. Parnell.

Mr. Campbell-Bannerman, replying to Mr. Healy—who asked if his attention had been called to the language used by Dr. Hall, the medical officer of Monaghan Workhouse, who was reported to have said at an Orange lodge over which he presided: "Some of them, perhaps, had read Parnell's utterances a few days ago at County Clare: 'You are the descendants of the men whom Cromwell sent to hell or Connaught. He only succeeded in sending you as far as Connaught.' He (Dr. Hall) considered it was a pity they did not get sent a little further"—said he had seen a letter from Dr. Hall, in which he explained that the language he used was not quite accurately reported in the *Monaghan Standard*. Dr. Hall said that his words did not point to the extreme alternative suggested in the question, and what he intended to convey was an expression of his opinion that it would have been for the good of the country if those who sympathise with the projects of the honourable member for Cork had gone across the Atlantic. Dr. Hall was not a public servant in the sense that his whole time was at the disposal of the public, and Mr. Campbell-Bannerman did not think the incident called for any further notice.

INSANITARY HOUSES.—The report of the Council of the London Sanitary Protection Society which has just been issued, states that of the 424 houses examined in the year 1884 two had drains entirely blocked up, seventy-five had leaky soil-pipes, fifty-six over-flow pipes from cisterns leading direct into drains or soil-pipes, and 211 waste-pipes from baths or sinks communicating untrapped with the sewer.

Obituary.

W. A. F. BROWNE, M.D., LL.D., &c.

ON the 2nd inst. the death occurred of Dr. W. A. F. Browne of Dumfries, in the eightieth year of his age. Born at Stirling in 1805, he was still an infant when his father, a lieutenant in the famous Cameronian regiment, was drowned while proceeding to the Peninsula on the outbreak of hostilities there, and the care of the child devolved upon his grandparents. By them he was placed first at the high school of his native town and subsequently at Edinburgh University. He distinguished himself at the University in many of the classes, and obtained his diploma in 1826. While in Edinburgh he was chosen to be President of various Societies, including the Royal Medical Society. It was about this time that Dr. Browne became fascinated by the new revelation of phrenology. George Combe was its chief prophet in this country, and Dr. Browne became the coadjutor and intimate friend of that extraordinary person. He studied with Combe, and lectured for him. In Combe's works there are frequent references to him; and the pupil and assistant whom he loved the master could also confide in, for he was named by Combe to be one of his trustees. After having taken his medical qualification Dr. Browne travelled on the Continent, and resided for a considerable period in France, where he acquired a thorough knowledge of its language, and studied psychology under the best known professors of that science. After an absence of several years he returned to Scotland, and about 1830 took up his residence at Stirling, where he commenced medical practice, and at the same time assisted at the Extra-Academical School of Medicine in Edinburgh. Though considerable improvements, forced by the exposure of the dreadful cruelties in Bethlem Hospital, had been effected in the treatment of the insane, medical reform in this direction was then still in its infancy. Dr. Browne's inquiries on the Continent and elsewhere led him to approach the consideration of the subject with the ardour of a specialist; his opinions were freely expressed, and he had not been long in practice in Stirling before he was offered an appointment as superintendent of the asylum at Montrose. Here he put in practice his theory with regard to the humane treatment of lunatics, anticipating the reforms at Lincoln, Hanwell, and other asylums in England, which took the shape of abolishing mechanical restraint; and the system which now obtains in every asylum throughout the land first assumed a complete form in Scotland when Dr. Browne went to Montrose. In 1839 he was invited to take charge of the Crichton Institution, Dumfries, a position which he accepted and held for eighteen years in spite of invitations from other quarters. But in 1858 Parliament passed a new Lunacy Act for Scotland. A Scotch Lunacy Board was established, and Dr. Browne was offered the post of Lunacy Commissioner. It was characteristic of the man that he disregarded the emoluments of the office (for he would have been richer by staying in Dumfries), and that he was ready to give up the comforts of an established home at the call of public duty. In his new office his ripened experience of the requirements of public asylums was of great value to the country, and he retained his position as Lunacy Commissioner until 1870, when, as the consequence of a carriage accident, he gradually lost his eyesight and gave up office to spend his last years in privacy in Dumfries. His mental vigour remained unimpaired, and he was enabled by the help of an amanuensis and reader to keep touch with the world and its progress. A thorough patriot, Dr. Browne was of course an enthusiastic admirer of Scotland's greatest sons. At the principal dinner on the occasion of the Burns Centenary in 1859 he presided and delivered a brilliant speech; at the Scott anniversary dinner he was one of the croupiers. In 1865 he was president of the Edinburgh Psychological Society. On his return to Dumfries he was appointed psychological consultant to the Crichton Institution.

ROYAL COLLEGE OF SURGEONS.—Professor H. A. Brailey, M.D., M.R.C.S., will commence his course of three lectures on "Some Points in the Anatomy and Physiology of the Eye," in the theatre of the College, on Monday next, the 16th inst., at 4 o'clock.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council on the 12th inst., the following gentleman, having previously passed the required examinations, and since attained the required age (twenty-five), received the diploma of Fellow:—

James Berry, Upper Bedford-place; date of Membership, Jan. 21st, 1882.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on the 5th inst.:—

Emmett, Richard, St. George's Hospital.
Inman, George Arthur Ferdinand, King's College.
Parr, Arthur Charles Edward, King's College.

THE Goldsmiths' Company have contributed £25 to the funds of the Hospital for Consumption, Hampstead.

THE Committee of Management of the Aberdeen Royal Infirmary have deputed two of their number to confer with the superintendent of the institution as to the alleged abuse of visiting privileges.

THE annual general meeting of the Royal Counties Veterinary Medical Association was held at Reading on the 27th ult., when Mr. W. G. Flanagan, President for the year, delivered his inaugural address.

ON the 9th inst., in the Queen's Bench Division, a surgeon's assistant, named Allen, recovered from his former employer, a medical man named Cook, £50 as damages for false imprisonment, he having been given into custody by the defendant on a charge of felony.

IMPORTANT experiments are being carried out by the Metropolitan Board of Works to meet the requirements of the Royal Commission on the state of the Thames and the main drainage of London. The sewage is poured into tanks, allowed to settle, and the deposit pressed into cakes.

THE committee of the Lambeth vestry, which recently reported against a proposal to plant trees on the roadsides of the great parish of Lambeth, although voluntary help of a substantial kind was forthcoming, have reconsidered the matter, and will now co-operate with the vestry in planting trees on suitable sites.

UNDERGROUND urinals and waterclosets have, says the *Engineer*, been constructed round the base of the Duke of Wellington's statue on the western front of the Royal Exchange, wholly beneath the street pavement and excavated in the mass of solid concrete surrounding the foundations of the base of the statue.

THE Public Health Committee of the Aberdeen Town Council have refused to allow a cargo of rags which arrived from Dunkirk at the time cholera was raging in France to be landed unless they are thoroughly disinfected, although the Board of Supervision's order relative to ships coming from infected ports expired on the 1st inst.

AT a meeting of the Anthropological Institution, on the 10th inst., Francis Galton, Esq., F.R.S., President, in the chair, Mr. James Frazer read a paper on "Certain Burial Customs as illustrative of the Primitive Theory of the Soul"; and the Director read a paper, by Admiral F. S. Tremlett, on the "Sculptured Dolmens of the Morbihan."

THE Luton Board of Guardians recently decided by a majority of two to grant the application of Professor Macalister that unclaimed bodies of paupers should be sent to Cambridge University Medical School for anatomical examination before burial. The subject had already been twice discussed, with an adverse result to the application; but the majority on the last occasion pleaded that the concession was in the interests of medical science.

ROYAL SURREY COUNTY HOSPITAL.—From the report which was read at the annual court of governors of this institution on the 28th ult., it appears that during 1884 594 patients were in hospital 20,273 days; the average to each patient was 34 days; average number in hospital daily, 57; there were 30 deaths, or 5·05 per cent.; 105 operations were performed; 3558 out-patients attended at the hospital 9440 times. The cash receipts for the year were £3724, against £3959 in 1883, when there was a special donation of £400. Towards the cost of the new building, the sum of £2500, or half the amount required, has been obtained.

TESTIMONIAL TO A MATRON.—It is proposed to present Miss Williams, the late matron of St. Mary's Hospital, on her retirement, with a testimonial, to consist of an engrossed vellum address with the names of the subscribers, and some personal ornament to be selected by herself. Subscriptions not exceeding one guinea may be sent to Mr. T. W. C. Jones, 6, Westbourne-street, Hyde-park, W.

ST. MARY'S HOSPITAL.—The annual dinner in connexion with St. Mary's Hospital Athletic Sports was given in the Venetian Room of the Holborn Restaurant on the 3rd inst. The chair was occupied by Mr. Malcolm Morris, surgeon in charge of the Skin Department of the Hospital, who was supported by Lieut.-Colonel Bird and by many members of the staff, among whom were Dr. Broadbent, Mr. Field, Mr. Norton, Mr. Owen, Dr. Philipps, Dr. Maguire, Mr. Juler, and others.

ROYAL LONDON OPHTHALMIC HOSPITAL.—At the annual general meeting of the governors of this institution on the 10th inst., the committee of management stated that in 1883 the beds occupied were 27,690, in 1884 there were 31,564. The number of out-patients treated was 23,568, the attendances being 117,840. The total receipts for the year amounted to £8024, which included annual subscriptions £758, donations £2741 (inclusive of the legacies). The expenditure amounted to £6767, but the liabilities outstanding amounted to £1311, so that the expenditure was largely in excess of the ordinary receipts. Increased contributions and donations were earnestly appealed for.

THE HOSPITALS ASSOCIATION.—The first annual meeting of the members and associates of this institution was held on the 11th inst., Sir Andrew Clark, Bart., M.D., presiding. Amongst those present were Dr. Bristowe, F.R.S., Dr. Gilbart Smith, General Keating, Mr. Henry C. Burdett, Mr. W. J. Nixon, Mr. N. H. Nixon, Sir Vincent Mercier, and Mr. J. L. Clifford Smith, hon. secretary. The secretary read the report, which was a highly satisfactory one, from which it appeared that though it was called the first annual report, it, in fact, really covered a period of nearly two years, steps having been taken as far back as 1883 to found the Association. The financial position of the Association showed a balance in hand of £160. The retiring officers were unanimously re-elected, and the meeting terminated with a vote of thanks to the chairman.

A COURAGEOUS ENGLISH NURSE.—American papers just received give full details of the late disastrous fire in the lunatic wing of the Philadelphia Hospital, in which nearly fifty patients lost their lives. All accounts agree in expressing very high appreciation of the cool and courageous conduct of Miss Alice Fisher, who lately resigned the appointment of Lady Superintendent of the General Hospital at Birmingham and proceeded to Philadelphia to take charge of the nursing department of the hospital in that town at the urgent request of the Board of Governors. Miss Fisher is well known to many members of the profession from having held the appointment of Lady Superintendent of Addenbrooke's Hospital, Cambridge, and the Radcliffe Infirmary at Oxford, at both of which institutions important improvements in the nursing arrangements were effected during her tenure of office.

Medical Appointments.

Intimations for this column must be sent DIRECT *to the Office of* THE LANCET *before 9 o'clock on Thursday Morning at the latest.*

ATKINSON, GEORGE THOMAS ANDREW, M.B., C.M.Ed., has been appointed Medical Officer for the Harrogate District of the Knaresborough Union, vice Ford.

CASSEL, CHARLES E., F.I.C., F.C.S., has been appointed Public Analyst for the Borough of Chipping Wycombe.

FIRMIN, CUTHBERT C., M.R.C.S., L.S.A.Lond., has been appointed Honorary Assistant-Surgeon to the Children's Hospital, Gloucester.

GABB, J. PERCY ALWYNE, M.D.Lond., M.R.C.S., has been appointed Honorary Assistant-Surgeon to the Royal Surrey County Hospital.

GARBUTT, J. GILLIOTT, M.A.Lond., M.R.C.S., L.S.A.Lond., has been appointed Surgeon to the South Metropolitan Gas Company, Bankside Works.

GARLIKE, E. WILLIAM BENNETT, L.R.C.P.Ed., M.R.C.S., has been reappointed Medical Officer of Health for the Cheshunt Urban Sanitary District.

HALL, ALFRED, M.R.C.S., has been appointed Medical Officer for the Butterton and Grindon District of the Leek Union.

HOGG, JAMES BALLANTYNE, L.R.C.P.Ed., L.R.C.S.Ed., has been appointed Assistant Superintendent of Hospitals for the Insane, Goodna and Sandy Gallop, Queensland.

LAKE, WELLINGTON, M.R.C.S., L.S.A.Lond., has been appointed a Surgeon to the Walthamstow Town Dispensary, vice F. A. Best, retired.

LOW, CHARLES, M.B., C.M.Ed., has been appointed Resident Medical Officer to the Southland Hospital, Invercargill, New Zealand, vice Wardale, resigned.

MILBURN, FRED. LE FEVRE, M.R.C.S., L.S.A.Lond., has been re-appointed Medical Officer for the Fourth District of the Holborn Union.

MOLYNEUX, MORRIS J., L.F.P.S., L.A.H., & L.M., has been appointed Medical Officer to the 8th Wimbledon District of the Kingston Union, vice Comber, resigned.

POLLARD, REGINALD, M.B.Durh., M.R.C.S., has been appointed Assistant House-Surgeon to the Western General Dispensary, Marylebone-road, N.W.

ROBERTS, ARTHUR HENRY, L.R.C.P.Lond., M.R.C.S., has been appointed Resident Medical Officer to Prince Alfred Hospital, Sydney.

ROSE, JAMES, M.R.C.S., L.R.C.P.Lond., has been appointed Honorary Assistant-Surgeon to the Liverpool Eye and Ear Infirmary, vice G. Stone, L.R.C.P., L.R.C.S., resigned.

SCHOLES, RICHARD BATTERSBY, M.B., C.M.Ed., has been appointed Inspector of Asylums for the Insane, Queensland. Also Superintendent of the Hospitals for the Insane at Goodna and Sandy Gallop, Queensland.

SMITH, EUSTACE, M.D., F.R.C.P.L., has been appointed Consulting Physician to the Merchant Seamen's Orphan Asylum.

TUCKER, JOSEPH, M.R.C.S., L.S.A.Lond., has been appointed Medical Officer for the Chawleigh District of the Crediton Union, vice Daly.

TURNER, PHILIP D., M.R.C.S., has been appointed Resident Clinical Assistant to the Hospital for Consumption, Brompton.

Births, Marriages, and Deaths.

BIRTHS.

BARRON.—On the 7th inst., at 8, Manchester-road, Southport, the wife of Herbert G. Barron, B.A.Oxon., L.R.C.P., &c., of a son.

BRANFOOT.—On the 7th ult., at Madras, the wife of Surgeon-Major A. M. Branfoot, Indian Medical Department, of a daughter.

EVANS.—On the 27th ult., at Sutton Coldfield, the wife of Alfred Evans, M.R.C.S., of a son.

GROOME.—On the 6th inst., at Stowmarket, the wife of W. Wollaston Groome, M.B., of a son.

MAISEY.—On the 9th inst., at Charlbury, Oxfordshire, the wife of F. T. Maisey, M.R.C.S., of a daughter.

RENSHAW.—On the 9th inst., at Clarendon-place, Citadel-road, Plymouth, the wife of Staff-Surgeon Burnard Renshaw, R.N., prematurely, of a son.

MARRIAGES.

BROWN—CARNEGIE.—On the 7th inst., at Penang, Straits Settlements, William Carnegie Brown, M.D., to Jane Ross, daughter of the late John Carnegie, M.D., of Chesterfield.

CADMAN—BELDER.—On the 26th ult., at Amsterdam, Arthur W. Cadman, M.R.C.S., of Mornington-crescent, N.W., to Johanna Jacoba Margaretha, second daughter of Hendrik Barend Belder, of Weteringschans, Amsterdam.

CURD—DOYLE.—On the 28th ult., at St. Paul's, Camden-square, by the Rev. E. Richards-Adams, Charles Curd, M.R.C.S., of Bath, to Charlotte Emily, second daughter of Watkin Doyle, of Camden-road, N.W. No cards.

HENRY—KIRKPATRICK.—On the 11th inst., at the Presbyterian Church, St. John's-wood, Richard Henry, M.D., Dublin, to Annie Louisa, daughter of the late Rev. W. B. Kirkpatrick, D.D., of Dublin.

MOODY—FRIEND.—On the 4th inst., at Worplesdon, James M. Moody Medical Superintendent Surrey County Asylum, Cane-hill, Purley, to Alice Harriet Friend, of Oaklands, Worplesdon, Surrey.

RICE—ROSS.—On the 4th inst., Richard Rice, M.R.C.S., L.S.A.Lond., of Harwell, Berks, eldest son of the Rev. Richard Rice, M.A., of Little Barrington, Gloucestershire, to Alexandria Agnes Helen, third daughter of Col. W. A. Ross, late R.A., of Acton House, Acton.

DEATHS.

COTTERELL.—On the 4th inst., after a short illness, at the residence of his relatives, Dr. and Mrs. Rayner, Great Malvern, Thomas Reginald Cotterell, M.R.C.S., L.S.A.Lond., late of Charlbury, Oxon, aged 69.

GARDINER.—On the 7th inst., Samuel Christopher Gardner, M.R.C.S., L.A.C., of Church-street, St. Marylebone, son of the late Mr. Christopher Gardner, of Burnham, Essex, in his 74th year.

HUGHES.—On the 3rd inst., at Beresford-road, Highbury, N., Henry William Hughes, M.R.C.S., late of Fenchurch-street, E.C., aged 62.

PYE-SMITH.—On the 9th inst., at Sevenoaks, Ebenezer Pye-Smith, F.R.C.S., aged 78.

THOMPSON.—On the 28th ult., at Bramble-hill, Honiton, Devon, P. H. Hansard Thompson, M.R.C.S., L.S.A.Lond., formerly of Monmouth, aged 80.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

METEOROLOGICAL READINGS.

(Taken daily at 8.30 a.m. by Steward's Instruments.)

Medical Diary for the ensuing Week.

Monday, March 16.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10.30 A.M. each day, and at the same hour.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M. each day, and at the same hour.

ST. MARK'S HOSPITAL.—Operations, 2 P.M., and on Tuesdays at the same hour.

HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.

METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.

ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.

MEDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Routh: The Alleged Constitutional Treatment of Diseases of the Uterus and its Appendages.—Mr. Walter Pye will show a case of Natural Repair after Gangrene of the Scrotum.

Tuesday, March 17.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at the same hour. Ophthalmic Operations on Mondays at 1.30 and Thursdays at 2 P.M.

ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.

WESTMINSTER HOSPITAL.—Operations, 2 P.M.

WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.

ROYAL INSTITUTION.—3 P.M. Prof. Gamgee: Digestion and Nutrition.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 P.M. Dr. Hermann Weber: Croonian Lecture on the Hygienic and Climatic Treatment of Consumption.

PATHOLOGICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Dickinson: Violet Pigment Discharge from the Mouth.—Dr. Samuel West: Aneurysm of the Splenic Artery rupturing through the Stomach.—Mr. Treves: A Congenital Deformity.—Dr. Turner: Superficial Slough in the Stomach (card); Growth of the Kidney invading the Vena Cava (card).—Dr. Silcock: Osteitis Deformans.—Mr. D'Arcy Power: Synovial Cysts in connexion with Joint Disease.—Mr. Battle: Primary Sarcoma of the Penis.—Dr. Norman Moore: Cavity in the Lung of an Infant; Renal Disease in an Ox (card).—Mr. Stephen Paget: Dislocated Hip.—Dr. Percy Kidd: Fatal Hæmoptysis from an Hydatid of the Lung.—Dr. Chaffey: Pyo-salpinx in a Child aged four years (card).

Wednesday, March 18.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.

MIDDLESEX HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.—Ophthalmic Operations on Tuesdays and Thursdays at 1.30 P.M.

ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Skin Department: 9.30 A.M., on Tuesdays and Fridays.

ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.

LONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.

GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Saturday, 2 P.M. Skin Department: 1.45 P.M.; Saturday, 9.15 A.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 3 to 4 P.M.

Thursday, March 19.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Surgical Consultations, 1.30 P.M.

CHARING-CROSS HOSPITAL.—Operations, 2 P.M.

CANCER HOSPITAL, BROMPTON.—Operations, 2.30 P.M.; Saturday, 2.30 P.M.

NORTH-WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

ROYAL INSTITUTION.—3 P.M. Prof. Dewar: The New Chemistry.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 P.M. Sir Andrew Clark: Lumleian Lecture on some Points in the Natural History of Dry Pleurisies.

HARVEIAN SOCIETY OF LONDON.—8.30 P.M. Mr. W. Adams Frost: The Early Treatment of Concomitant Squint.—Mr. F. Treves: Resection of the Intestine.

Friday, March 20.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1.30 P.M.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—7.30 P.M. Ballot. Mr. A. Wynter Blyth: The Action of Disinfectants on Micro-zooides.

ROYAL INSTITUTION.—9 P.M. Prof. A. W. Rücker: Liquid Films.

Saturday, March 21.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

ROYAL INSTITUTION.—3 P.M. Mr. C. Armbruster: Richard Wagner.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editor."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe, or recommend practitioners.

Local papers containing reports or news-paragraphs should be marked.

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

CONJUNCTIVÆ INSENSITIVE TO COCAINE.

DR. OSIO, in a series of articles on cocaine in ophthalmic practice in a Spanish medical journal, says: "There are conjunctivæ which are uninfluenced by cocaine. In the case of a lady with a completely normal conjunctiva who was suffering from posterior adherence of the whole iris I instilled a 4 per cent. solution five times at intervals of four minutes, without the slightest effect on the conjunctiva. The cornea was, however, thoroughly anæsthetised. I have employed a solution of the hydrochlorate of cocaine, 4 per cent., in English glycerine, and have obtained the same results as with an aqueous solution."

J. L.—We regret to differ from our correspondent; but if his views were adopted progress would be impossible, and any change, however beneficial to the interests of the public, would be resisted on the grounds that it interfered with the supposed rights of individuals. When vested interests are involved, fair compensation should be given.

CASCARA SAGRADA IN OBSTINATE CONSTIPATION.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Lucas's letter in your issue of Feb. 21st, drawing attention to the compound cascara pills which I prescribed for him, I wish to supplement his list of ingredients by the addition of capsicum, which formed a most important part of the preparation from which he derived such "marked benefit." I should not trouble you with this communication were it not that after three years' experience of cascara sagrada I attach the greatest importance in most cases to its combination with capsicum. I do this, first, because capsicum, more than any other ingredient, does away with that griping which is a great drawback to the general use of cascara sagrada; and, secondly, owing to its action as a hepatic and gastro-intestinal stimulant, it supplements, and, in supplementing, renders necessary a smaller dose of, the more active and acrid ingredient.

I may add that I have prescribed these pills, to the exclusion of all other preparations of cascara sagrada, now for some time with the greatest benefit to my patients and satisfaction to myself. Most other preparations I had previously tried, and was somewhat disappointed in the trial; many griped, some were inert, while others (fluid preparations, which many patients object to for various reasons) had a most disagreeable after-taste. Whatever preparation be used, or whenever this drug is prescribed, it is absolutely necessary, if we want to avoid disappointment, when the chemist obtains a new supply, that the physician should test for himself, and, if possible, on himself, its purity and power; for it may be said without fear of contradiction that there is no drug in the market so variable in these respects. This I invariably do, with the result that I can now thoroughly rely on the efficacy of these pills as made up for me by Messrs. Twinberrow and Son; for I have found them the only preparation of the drug that complies with the threefold necessity of a good prescription—viz., *Curare cito tuto et jucunde.*

I have the honour to be, Sir, your most obedient servant,

Welbeck-street, W., Feb. 27th, 1885. D. H. CULLIMORE, M.D.

To the Editor of THE LANCET.

SIR,—Adverting to my note on cascara sagrada (THE LANCET, Feb. 21st, page 369), I would desire to remark on its pathological properties that, in sufficiently full doses, it is a powerful intestinal stimulant, acting, I imagine, more on the small intestines, and producing copious watery evacuations, preceded by intense griping, if not guarded by some such drug as belladonna. It is also, I am inclined to think, a feeble hepatic stimulant, for clay-coloured stools become more or less tinged with bile; but, of course, this latter action may, *cæteris paribus*, be due more to the intestinal than to the hepatic stimulation. Such being my further experience of this new drug on myself and others, I deem it not uninteresting to place the same on record.—Yours truly,

March 11th, 1885. JOHN LUCAS, M.D.

THE WHITTLE HUTCHINSON FUND.

ON the 5th inst., at an ordinary meeting of the Liverpool Medical Institution, the President (Dr. Gee) presented Drs. Whittle and Hutchinson with a cheque for a little over £169, the outcome of the fund started in November last to express the sympathy of the profession towards these gentlemen in their vexatious action at law in the case of Goode *v.* Whittle and others. Drs. Ewing Whittle, Glynn Whittle, and Hutchinson returned thanks, expressing themselves as deeply grateful for the sympathy evinced by their brethren, and for the token of that sympathy which they had just received. Below are the names of subscribers whose subscriptions have not yet been publicly acknowledged.

Corpuscle.—Our correspondent will find an excellent essay on the subject, with several references to other sources of information, in Essays on Physiological Subjects, by Gilbert W. Child; published by Longmans, 1869.

Medicus (Portsmouth) had better apply to the author of the card, Dr. Angus Mackintosh, Chesterfield.

Dr. J. J. Monteath.—The reply was given in our issue of Feb. 14th, p. 323.

FEES FOR SCHOOL BOARD CERTIFICATES.

To the Editor of THE LANCET.

SIR,—A few days ago a boy I am attending gratuitously brought to me a form, drawn out and partly filled up, as follows:—

"SCHOOL BOARD FOR A.....

"March 8th, 1885.

"I hereby certify that Albert H....., residing at ..... is unable from illness to attend school for ..... days from this date.

"Signed ....., Medical Attendant.

"This notice must be taken to the medical attendant for his signature, and then sent directly to the School Board visitor."

Knowing that this Board has refused on former occasions to pay for certificates, I delayed signing until I inquired if it would pay in this instance. I am told that it will not, and therefore I have not certified. The fee I claim is 2*s.* 6*d.*; and what I wish to know is, if on a future occasion such a form should be brought to me, and I sign it, can I recover in a county court? for I quite agree with you, that "when public authorities require professional opinions they must learn to pay for them." I am, Sir, yours faithfully,

March 9th, 1885. M.R.C.S.Eng., L.S.A.

L. H. N.—We do not think there is any hardship in the case. The conditions of employment were clearly laid down, and the acceptance of them was optional.

REMOVAL OF A PORTION OF A GUN-BARREL FROM THE NOSE

To the Editor of THE LANCET.

SIR,—I think I remember a case reported in your journal of the removal of a portion of a gun-barrel under nearly, if not precisely, similar circumstances to those reported in your issue of Feb. 28th. If my memory serves me, it was by Professor Syme in Edinburgh; it was illustrated by a wood-cut, too, and was larger than the piece extracted so successfully by Mr. Rushton Parker.—Yours faithfully,

Mansfield, Notts, March 6th, 1885. THOS. GODFREY.

M. O. H. had better submit his question to E. Hammond, Esq., 2, Barton-street, Westminster.

Dr. J. P. Lynch (Ann Arbor).—The gentleman's name does not appear in the Medical Directory.

REMOVAL OF SUPERFLUOUS HAIR BY ELECTROLYSIS.

To the Editor of THE LANCET.

SIR,—May I ask through your columns for a means of removing surplus hair by electrolysis? Where can I see such a plan in action? I have a lady patient with a growth of hair on her face, and she wishes it permanently eradicated. I am Sir, yours truly,

Claremont-sq., N., March 12th, 1885. T. R. ALLINSON, L.R.C.P.Ed.

THE INSANE POPULATION OF THE UNITED STATES.

DR. W. B. SYLVESTER, Willard, N.Y., in a paper which appeared recently in the *Alienist and Neurologist* states that twenty years ago the number of insane persons in the United States was only 24,042. In 1870 it had reached 37,432, and in 1880 humane treatment was required for 91,959 lunatics. From 1870 to 1880 the increase in insanity was over 100 per cent., while that of the total population was about 26. These figures do not represent an actual increase, but during this period a large number of insane persons, previously concealed, were brought to public notice by more thorough investigation. In America, apart from several large county asylums, there are eighty State and forty private institutions for the care of the insane, with a capacity for about 40,000, but accommodating 53,192, thus leaving probably 45,000 to be cared for elsewhere. The proportion of insane is greatest in New England, whilst the increase has been most rapid in the Western States. In the State of New York there are thirty-five institutions for the care of these unfortunate people, accommodating 11,343 patients, while it is claimed that there are 4000 provided for at home.

M.R.C.S.—We think, under the circumstances, it was wise to call in another medical man. No legal claim could be made to a larger fee than the one received.

"KING AND QUEEN'S COLLEGE OF PHYSICIANS, IRELAND."

To the Editor of THE LANCET.

SIR,—A letter on the above subject appeared in your issue of Feb. 21st. Your correspondent has my most earnest sympathy. I also am possessed of the "L.K.Q.C.P.I.," but have, since I have been in practice in England, ceased to take advantage of the distinction—not enjoyed by London graduates—of having half the alphabet after my name, reminding one, as a facetious friend of mine remarks, more of the qualifications of Colman's "Dr. Pangloss" than a hard-working practitioner who tries to make a living by virtue of his abilities. Outside the narrow circle of Irish physicians very few understand the meaning of the mysterious hieroglyphics that are an object of ridicule to so many. If the College authorities would devote their energies to elevating the status of the corporation, instead of wasting time by agitating for individual advancement, they would contribute far more to popularise the College, not only among Irish physicians practising out of the country, but also with English and Scotch seekers for a medical qualification. Until the Irish College becomes a Royal College, all attempts at reform can only serve to bring the institution into contempt.—Yours truly,

March 3rd, 1885. AN IRISH GRADUATE.

To the Editor of THE LANCET.

SIR,—The plea for simplification by abbreviation of the above title urged by "Surgeon R.N." is well worthy of consideration by the powers that be. The plea is based on the well-founded fact that these titular letters are to the public outside of Dublin incomprehensible, and to members of the profession other than those in Ireland even as a Chaldaic inscription. So it comes about that the holders of this otherwise honourable diploma are, in England, ashamed to acknowledge their college for fear of derisive laughter, and at the first opportunity are compelled to take the "L.R.C.P.," the meaning of which letters is "understanded of the people." I submit that to attach to a name symbols which are meaningless to the uninitiated is ridiculous, and tends directly to lower the monetary and social value of the diploma. Brevity should as often as possible rule all titles. Life is too short to have to append the letters L.K. & Q.C.P.I. to one's name.

I am, Sir, yours truly,

Feb. 28th, 1885. M.D.

Country Surgeon.—A Poor-law medical officer is not bound to attend any of the poor patients our correspondent speaks of without an order. Of course, if anything untoward should result from his refusal, he is likely to incur public odium; but this is only one of the drawbacks of practising in a poor neighbourhood. The best plan to adopt in such cases is to go *once* in any case of emergency, and direct the patient or his friends to get an order for the attendance of the district medical officer for after-treatment.

SMEARING THE LARYNGOSCOPIC MIRROR WITH GLYCERINE.

To the Editor of THE LANCET.

SIR,—Dr. Neale, the very distinguished and able author of the Medical Digest, has written to me stating that in Sect. 611:3 of that work Dr. Buzzard taught that the mirror should be smeared with glycerine. I am sure that I claimed no originality for the idea, as I thought everybody knew it. But it appears not. I now bring before you another method of preventing the breath condensing upon the mirror, which I have learnt from dentists, and which, I believe, is not in the Digest—namely, to smear the mirror with the patient's saliva by rubbing it upon the inner side of the cheek, this being the method pursued by dentists when using a mirror in stopping, &c.

I am, Sir, yours truly,

Bicester, March 11th, 1885. EDWARD COTTERELL.

Dr. Corazza of Verona is referred to the Transactions of the Neurological Society of Philadelphia; but Dr. Weir Mitchell would no doubt give him fuller information if he were written to on the matter.

PORTABLE ELECTRIC LIGHT FOR HOUSES.

THE *Electrician* states that Messrs. Blumberg construct an electric incandescent lamp, worked by a Skrivanow battery, which contains zinc, chloride of silver, and a solution of potash, the whole being as portable as an ordinary china oil-lamp. A lamp of twenty-five-candle power is said to burn for twelve hours without attention at a cost of eightpence.

W. A. G.—1. No.—2. Yes.—3. Attendance at a colonial hospital with more than 100 beds is recognised by the English Colleges.

Mr. William Fraser, M.B.—We know nothing of the society in question.

"SWEET SPIRITS OF NITRE."

To the Editor of THE LANCET.

SIR,—In your last issue appeared a paragraph under the above heading. It is not for me to express an opinion as to whether the therapeutic value of the *spiritus etheris nitrosi* and kindred preparations is really due to the nitrous ether contained in them, but it is evident that manufacturing chemists have no right to change the method of manufacture of a well-known preparation in such a way as essentially to alter its composition. This, however, is done by those manufacturers who make a preparation of ·900 specific gravity. This figure indicates the presence of something like 25 per cent. of extra water, whether it be directly added as such or be due to the distillation being pushed to an extreme. A preparation of this density will undergo decomposition comparatively rapidly, with destruction of the nitrous ether contained in it; and the same remark applies, in a somewhat less degree, to the preparation having a density of ·887, which is stated in your columns to be an article supplied by a large manufacturer, principally to medical men. Medical men should know that the presence of excess of water causes rapid deterioration of spirit of nitrous ether. If they desire a preparation containing nitrous ether, and one on which they can rely, let them in future insist on being supplied with a spirit having a density of ·845, and containing not less than, say, 2½ per cent. of real nitrous ether. Till recently the estimation of nitrous ether in preparations containing it was a troublesome, and to some extent an uncertain, operation; but this is no longer the case, for by a method described by me in a recent number of the *Pharmaceutical Journal* (Feb. 21st, 1885, page 673) it is possible for any medical man to assay his spirit of nitrous ether in a few minutes, and without the use of any out-of-the-way reagents or solutions of known strength.

I am, Sir, yours faithfully,

ALFRED H. ALLEN, F.I.C., F.C.S.,
Public Analyst for the Borough of Sheffield,
Sheffield, March 9th, 1885. West Riding of Yorkshire, &c.

Mr. James Cross (Wimborne) should make application to the Secretary of the Northampton Provident Dispensary.

Dr. Rogers' letter arrived too late for insertion this week.

"A NEW FORM OF BLOTTING SHEET AND OF MEDICAL ADVERTISEMENT COMBINED."

To the Editor of THE LANCET.

SIR,—In reference to your paragraph of last week, I hasten to give the explanation asked for.

Several gentlemen in the City, having noticed that there was no institution of a provident nature not eleemosynary by which City clerks could obtain medical advice by a fixed annual payment, so avoiding the serious trouble which the payment of ordinary medical fees entail on persons of small means, have determined to try if an entirely self-supporting association would not be treated with welcome by the class for which it was intended. When it is considered that many provident dispensaries have been established to provide not only medical assistance but medicine also, at a much lower rate, it cannot be thought that the annual fee now named is too low when medicine is not provided, but only the right to consult the medical officers at their consulting-rooms. The original promoters having applied to three medical men having consulting-rooms in the City, they agreed to act as medical officers if their names were not advertised, as they thought that a non-dispensing association of the kind, while not interfering with the legitimate business of the City chemists, would tend to reduce the present enormous amount of counter practice by entirely unqualified men. I have, in conclusion, to say that every effort will be made to issue cards only to clerks, warehousemen, and others, for whom the association has been founded.—I am, Sir, yours truly,

H. D. H. CHARLTONE, Secretary.

The City of London Medical and Surgical Association,
13, Size-lane, E.C., March 9th, 1885.

E. R. W.—It would be hardly fair to criticise the utterance of a speaker on a scientific question simply upon a newspaper report.

HOW TO CARRY, UNAIDED, AN INSENSIBLE MAN.

To the Editor of THE LANCET.

SIR,—Officers in the Soudan, and also in South Africa, have written to me by the last mail, asking, "Which is the best way to lift and carry by oneself, unaided, an insensible man?" As such a contingency is likely to occur at any moment to any officer or man in the service, perhaps one of your experienced correspondents would kindly reply in THE LANCET, giving some details of the best mode of lifting and carrying an insensible man unaided. I am, Sir, yours obediently,

March 9th, 1885. R. N. R.

J. S. O.—1. The coroner is not authorised to pay fees to medical officers of public hospitals, and magistrates are quite within their right in refusing to allow such fees. There is high legal opinion, however, that "workhouse infirmaries" do not come within the definition "public hospitals," although in practice it is customary to regard them as if they did.—2. In case of grievance the proper course is to apply to the Home Secretary.—3. Our correspondent is compelled by his subpœna to give evidence of facts within his knowledge. We advise an appeal to be made to the Home Secretary for his interpretation of the point raised in paragraph 1.

Dr. G. M. Sternberg (Baltimore).—In an early number.

An Army Doctor has not enclosed his card.

CONSTANT TINCTURES.

To the Editor of THE LANCET.

SIR,—Having made tinctures for thirty-five years, I can with certainty say that if good sound drugs are used and the proof or rectified spirit, as the case may be, is up to the mark, the strength of the tinctures will for all therapeutical purposes be sufficiently uniform and trustworthy. It has been my custom to take the specific gravity of each batch of all the more active tinctures, and I have rarely found any appreciable difference in the respective batches. If inferior drugs are used, "the careful addition of crude drug or spirit," as suggested in your article on Pharmacology, would be necessary.—I am, Sir, yours faithfully,

March 9th, 1885. E. W., L.S.A.

COCAINE FUNGUS.

To the Editor of THE LANCET.

SIR,—In your issue of Jan. 31st one of your correspondents mentions the formation of a fungus which he found on the surface of some 4 per cent. cocaine solution, and which he considered in a great measure destroyed its anæsthetic properties. The surgeons at this hospital use it almost daily, and when the solution becomes flocculent or thick, I filter it through animal charcoal, and add a few grains of salicylic acid, and I find the filter solution as good as when first made. I think it should be kept in a cool place, and away from sunlight.—Yours faithfully,

J. CHURCHYARD,

Sussex Eye Hospital, Brighton, March 5th, 1885. Dispenser.

A QUERY.

To the Editor of THE LANCET.

SIR,—Could you or any of your readers tell me of a home, within easy reach of London, where an elderly gentleman who has lost his eyesight could be received at a moderate rate? Any information on the subject will be most thankfully received.—Yours faithfully,

Seymour-street, W., March 10th, 1885. ALEX. BOWIE, M.B.

ERRATUM.—By a clerical error in our Dublin correspondent's letter of last week, Dr. McCabe was stated to have been appointed a medical "commissioner" to the Irish Prisons Board. It should have been medical *officer*.

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Sir Andrew Clark, London; Mr. Rushton Parker, Birmingham; Mr. Howard Marsh, London; Dr. Heywood Smith, London; Mr. G. E. Walker; Mr. J. M. Lucas, London; Dr. Wickham Legg, London; Dr. Angus Mackintosh, Chesterfield; Mr. Cowell, London; Brigade-Surgeon C. Macdowall; Mr. W. Fraser, Ashburton; Dr. J. C. Murray, Newcastle-on-Tyne; Mr. A. H. The Publisher cannot hold himself responsible for the return of testimonials, &c., sent to the office in reply to advertisements; copies only should be forwarded.

NOTICE.—Advertisers are requested to observe that it is contrary to the Postal Regulations to receive at Post-offices letters addressed to initials only.

An original and novel feature of "THE LANCET General Advertiser" is a special Index to Advertisements on page 2, which not only affords a ready means of finding any notice, but is in itself an *additional* advertisement.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Answers are now received at this Office, by special arrangement, to Advertisements appearing in THE LANCET.

Terms for Serial Insertions may be obtained of the Publisher, to whom all letters relating to Advertisements or Subscriptions should be addressed.

Advertisements are now received at all Messrs. W. H. Smith and Son's Railway Bookstalls throughout the United Kingdom, and all other Advertising Agents.

Tables of Contents, with the Index of Advertisements, for each Number can be had on application to the Publisher.

Agent for the Advertising Department in France—J. ASTIER, 66, Rue Caumartin, Paris.

Gulstonian Lectures
ON
MALIGNANT ENDOCARDITIS.

Delivered at the Royal College of Physicians.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF CLINICAL MEDICINE AT THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

LECTURE III.

MR. PRESIDENT AND GENTLEMEN,—Few diseases present greater difficulties in the way of *diagnosis* than malignant endocarditis, difficulties which in many cases are practically insurmountable. It is no disparagement to the many skilled physicians who have put their cases upon record to say that in fully one-half of them the diagnosis was made post mortem. In spite, too, of able memoirs in the journals, the disease has not been much known, and it is only of late years that the text-books have contained chapters upon it. The protean character of the malady, the latency of the cardiac symptoms, and the close simulation of other disorders combine to render the detection peculiarly difficult.

In the group of cardiac cases in which the disease attacks a patient the subject of chronic valvulitis the matter is usually easy enough. The existence of fever of an irregular type, and the occurrence of embolism, generally suffice to make the case clear. It must be remembered that simple warty endocarditis not unfrequently attacks sclerotic valves, and may be accompanied by slight fever. Of course, in chronic heart disease, irregular pyrexia may arise from other causes—local suppuration, cellulitis, &c.,—which must be excluded.

In rheumatic fever, a disease in which the heart is more systematically examined than any other, if with the occurrence of a murmur the symptoms become aggravated and assume a typhoid or pyæmic type, the recognition of the complication should be easy. The onset of severe head symptoms in rheumatism—delirium, with high fever and coma - requires to be carefully distinguished. Fortunately, the simple endocarditis so common in this disease rarely, as I shall have occasion to show, passes into the grave form.

In pneumonia, a prolongation of the course, with the supervention of typhoid or septic symptoms, should lead to a very careful examination of the heart.

The greatest difficulty is met with in those acute cases resembling the malignant forms of the fevers; here the affection may simulate typhoid, typhus, cerebro-spinal meningitis, or even hæmorrhagic small-pox. Even with the detection of a heart murmur, the judgment may have to be suspended, and many cases die with the general symptoms of profound blood-poisoning, before the development of any special features upon which a diagnosis could be based.

From typhoid fever, with which the cases are most often confounded, the mode of onset, the pyrexia, and the abdominal symptoms offer the chief points for discrimination. The onset of severe endocarditis is more abrupt, not so often preceded by a period of failing health and progressive weakness. In a large number of cases, cardiac pain or oppression and shortness of breath are mentioned as early symptoms. The fever rarely presents, in the early days of the disease, the regularity of typhoid, and from the outset may be very high. A sudden fall to the normal, or even below, may occur; indeed, irregular pyrexia is one of the most important diagnostic signs. The combination of diarrhœa, abdominal distension, and a rose-coloured eruption, points strongly to typhoid. The rash, when present, is usually petechial, a rare circumstance in typhoid fever. The development under observation of pronounced murmurs, particularly of aortic and regurgitant, is most suggestive of malignant endocarditis, and the occurrence of emboli would be a positive confirmation. Rigors rarely occur in typhoid, while they are common in endocarditis. It is well, however, to bear in mind that, in many of the most severe cases, death may occur, as in any of the infective disorders, without the development of the special symptoms necessary for a diagnosis.

Many of the cases present the clinical features of pyæmia, a condition which may actually exist, dependent upon the ulcerative lesions on the valves; and here the diagnosis lies between an ordinary septic infection from a wound, or auto-infection from a primary endocardial inflammation.

It is interesting to note the similarity of those cases of acute endocarditis in which death occurs in a few days, without the development of any other than the valvular lesion, with those instances of rapidly fatal acute periostitis and necrosis, and also with those cases of malignant septic infection from a slight external lesion.

It seems strange that difficulties should arise in the diagnosis between malaria and malignant endocarditis, but the records of cases plainly show that for weeks or months a condition of intermittent pyrexia may occur, simulating every type of ague. The paroxysms in regularity, in order of sequence, and in the accompanying general conditions, may fulfil every condition of a quotidian or tertian intermittent; and the development of cardiac symptoms, with breathing of the pyrexial type, may alone determine the nature of the case.

Etiology and Pathology.—With a view of obtaining data upon which to base statements regarding the etiological relations of malignant endocarditis, I have gone over the records of 209 cases. As before stated, thirty-seven of these occurred in connexion with pyæmia, traumatic or puerperal. Doubtless this number could have been very greatly increased had I examined files of special gynæcological and surgical journals, but my investigation did not lie so much in these directions. In forty-five cases there was no record of any previous disease which could be taken into account as possibly connected with the endocarditis. In 127 cases there was a history of past or existing disease with which the cardiac trouble could, with a greater or less degree of probability, be associated.

One or two general considerations may first be mentioned. The period of middle life gives the greatest number of cases. Young children are rarely the victims; there were only three or four instances under ten years of age, and not many more over fifty. The cases occurring in connexion with rheumatism presented an average younger age than the others; there were thirty-six instances under thirty years of age, out of fifty-one cases in which this point was mentioned. Of 160 cases (exclusive of traumatic and puerperal), ninety-nine were in males, and sixty-one in females. Persons debilitated by exposure or other causes, or addicted to drink, seem particularly liable to be attacked, and in such subjects, during the course of an acute disorder, this complication is much more likely to arise. As has been already referred to, the existence of sclerotic valvulitis is a very important factor in the etiology of severe endocarditis, a very considerable proportion of the cases occurring in individuals whose valves are thickened and crumpled from chronic inflammation.

The existence of a primary protopathic endocarditis must, I think, be allowed. In forty-five cases no history could be obtained of rheumatism or other affections with which endocarditis is known to be associated. Many of these cases were of the most malignant type; in ten, death took place within a week. A specific statement of the absence of rheumatism was generally given. The onset was usually like that of a specific fever—headache, vomiting, rigors, pyrexia, and often early delirium and unconsciousness. The very acute cases resemble severe typhoid or typhus, but, when more prolonged, a pyæmic condition may develop. In a number of these cases the disease has attacked persons with chronic valve disease, some while under treatment, others in whom the compensation was complete and the old lesions only detected at the necropsy. In five instances, the ulcerative process attacked aortic valves, two of which were fused, and had undergone the fibroid changes always associated with this malformation. In 127 of the cases, the endocarditis was associated with other diseases, some of the most important of which we shall now proceed to consider.

Rheumatism.—Since Bouillaud called special attention to the frequency of cardiac complications in this disease, its importance in the etiology of endocarditis has been universally recognised. And as regards the simple form of endocarditis, the general statements are quite true, but, fortunately, the graver and fatal form is much less common, much less, I think, than is usually supposed. In fifty-three cases there was a history of rheumatism, past or present. I included every case in which there had been the record of an attack, recent or remote. In only twenty-four did the symptoms of severe endocarditis arise during the progress of the acute or subacute disease. In twenty-nine cases there was simply a history of rheumatism, often years before, and

no mention of the occurrence of joint troubles at the time of the development of the endocarditis. Dr. Ogle called attention to the fact that ulcerative endocarditis occurred very often in persons in whom no rheumatic history could be traced. Of twenty-one cases which he reported, some of which were probably atheromatous, in only three was rheumatism mentioned. In only three also of the Montreal cases was there any positive history of rheumatism, either before or during the attacks. The following case, under the care of Dr. Ross, is a good example of the mode of onset.

B. M ——, aged twenty-two, a healthy girl until three weeks before her admission to hospital, on Jan. 4th. At that time she was attacked with rheumatism of the wrists and ankles, not very severe, and she did not receive any treatment. A week from the beginning of the attack she began to have chills, two or three a day, and she became feverish. During the next week she got worse, had occasional chills, not delirious; was brought to hospital on the 4th, in a very low state. On the 5th there were delirium and incoherence. Pulse 130; temperature 100°. Double murmur up and down sternum, joint troubles not evident. On the 6th, 7th, and 8th, remained in the same state, no chills; temperature ranged from 100° to 102°. On the 9th more restless. On the 11th a grey membrane was noticed on the fauces. On the 12th the membrane in throat had extended, and covered the soft palate. Temperature 103°. On the 13th she died suddenly. The necropsy revealed a large deep ulcer at the aortic ring, nearly destroying one segment, and penetrating deeply between the auricle and the left ventricle. There were small infarcts in the brain, extensive recent diphtheria of fauces.

In a larger number than in any other group, sclerotic valves were found, with the existence of which the past rheumatism could, in many instances, be connected. A primary rheumatic endocarditis was recognised by Latham, also by Graves and Stokes, and it is quite possible that some of the cases which I have grouped as protopathic represented instances of the kind in which, if life had been prolonged, joint troubles might have supervened.

Cases of acute rheumatism sometimes occur in which there may be multiple miliary abscesses,[1] and a pyæmic condition similar to the case just narrated, but without the presence of endocarditis. Micrococci have been found in these abscesses, and the cases resembles those rare instances of idiopathic pyæmia. It is worthy of observation that a skin eruption was most frequently noted in connexion with the rheumatic cases, generally an erythema. In a case of Dr. Kirkes,[2] it was observed on both face and hands. The occasional presence of a scarlet rash in rheumatism,[3] and in puerperal fever [4] has long been recognised.

In chorea, with which simple endocarditis is so often associated, the malignant form very rarely supervenes.

Pneumonia, as Bouillaud pointed out, is not unfrequently complicated with endocarditis, but the important part which it plays in the etiology of the malignant disease has not been generally recognised. In the cases I have reviewed, it stands at the head of the list of diseases in which secondary endocarditis of a severe nature develops, fifty-four instances having been noted, rather more than 25 per cent. of the total number of cases. For this I was quite prepared by our Montreal experience, for, in eleven of the twenty-three cases, the attack was associated with pneumonia. Of the occurrence of acute endocarditis in this disease, the statements are somewhat diverse. Bouillaud thought that, in a third or fourth of the cases in which there was left-sided pneumonia, there was inflammation of the serous membranes of the heart. Grisolle, in his classical work on pneumonia, states, on the contrary, that it is a rare complication, and this would certainly appear to be the conclusion of the Committee for Collective Investigation, for, in the report upon 1000 cases, endocarditis is only once mentioned. My experience at the Montreal General Hospital is very different. I have notes of 103 necropsies on cases of lobar pneumonia, and the occurrence of acute endocarditis is noted in sixteen cases, over 15 per cent. Of these cases eleven were of the malignant form. An analysis of these shows that in six the left lung was involved; in five, the right; in four, the upper lobe was affected; in seven, the lower. In nine of the cases there was pericarditis; in five of the eleven cases there was suppurative cortical meningitis. In the fifty-four cases which I have reviewed, in thirty-six the lung affected was mentioned, and in twenty-six the affection was on the right side, and only ten on the left, figures which are opposed to the statement of Bouillaud, that it is in left-sided pneumonia that endocardial complication most frequently supervenes. In fifteen cases acute meningitis is mentioned, and in one instance the meninges of the cord were also affected. The aortic valves seem more often involved than the mitral. In seventeen instances there were old sclerotic changes in the valves.

The clinical features of several cases in which the endocarditis came on during pneumonia have already been given. In many of them, as in the woman M. D ——, aged twenty-nine, referred to in the second lecture, the patients are brought to the hospital unconscious, and die within a few days, with symptoms of a grave cerebral disorder. In others there is a history of ordinary pneumonia, and the case may pursue the usual course, and defervescence take place, when in a day or so fever of an irregular type recurs, and typhoid or pyæmic symptoms appear. The majority of the cases are of this kind. Again, some instances occur in connexion with injuries, and the patients succumbs to a lobar pneumonia and endocarditis unconnected with any sepsis. Two of the Montreal cases were of this kind. In three or four cases there were rheumatic symptoms preceding or accompanying the pneumonia, as in a case of Dr. Mussers.

Elderly persons were more often attacked than in the other groups. There were ten individuals over fifty years of age. In the Montreal cases three of the patients had had pneumonia before; in one it was the third attack, and in every one of them there was a history of either drinking habits or previous bad health. In some cases, the pneumonia had partially or entirely resolved at the time of death, in others there was red, or, more frequently, grey hepatisation.

The relation of the meningitis to the pneumonia and the endocarditis is particularly interesting. The occasional occurrence of this complication in pneumonia has been referred to by many writers, particularly Grisolle, Huguenin,[5] and Greenfield.[6] In the 103 cases I met with it in eight instances, in five of which there was also endocarditis. The frequency of the association of these two conditions in pneumonia is illustrated by the figures already given; of twenty-five instances of meningitis in malignant endocarditis, fifteen cases occurred in pneumonia. In all the specimens I have examined, there were micrococci in the exudation, and in three cases many of the capillaries and small arteries were filled with them; and it seems natural, where the endocardium is involved, to attribute the process to embolism from the valves. But the occurrence of an identical cortical meningitis without any valvulitis shows that it may be due to other causes than the endocarditis. As Huguenin suggests, it may be dependent upon the presence in the blood of infective material derived from the infiltrated lung tissue.

In connexion with these secondary or consecutive inflammations in pneumonia, it is interesting to call to mind the not unfrequent occurrence of pericarditis, and of croupous inflammation of the gastro-intestinal canal. Dr. Bristowe some years ago noted the frequent complication of croupous colitis; and, in 103 necropsies, I have met with this complication in five instances; and in one there was extensive croupous or membranous gastritis.

Diphtheria is rarely complicated with endocarditis, and I have been able to find only two or three instances in which severe symptoms were present; yet in some works endocarditis is stated to be not an uncommon sequence. Labadie-Lagrave[7] regards it as such; but it is probable that what he described as vegetations are only Albini's little nodules, the remnants of fœtal structures. In 108 necropsies in diphtheria Telamon[8] did not meet with a single case of endocarditis; and my experience has been the same in thirty post-mortem examinations, many of which were in adults.

In dysentery a few cases have occurred. Litten[9] has recorded an instance in which there was extensive ulceration of the aortic valves; and one of the Montreal cases occurred in connexion with acute colitis.

In the eruptive fevers grave endocarditis occasionally develops—in typhoid, in scarlet fever, and in variola; but in the cases I have analysed these diseases appear of very trivial etiological significance.

In ague, as Lancereaux[10] first pointed out, simple or severe endocarditis may develop. In some of these cases, as in the remarkable one reported by Dr. Bristowe, to which I referred in the second lecture, the paroxysms of true intermittent, and those of the ulcerative endocarditis, seem to run the one into the other.[11] In most of the cases there has been only a history of severe ague, and the endocarditis has followed repeated attacks. Dr. Greenhow[12] has reported a very instructive case of the kind.

Dr. Goodhart[13] makes the interesting suggestion that ulcerative endocarditis is more frequently met with at periods in which scarlet fever, erysipelas, pyæmia, and diphtheria prevail. The Guy's Hospital records certainly seem to show that the cases appear in groups pretty close together, and at a time when the diseases mentioned are epidemic. In Montreal we have had occasionally a "run" of cases together, but I have not noticed the connexion referred to by Dr. Goodhart.

I approach a discussion of the pathology of malignant endocarditis with some trepidation, partly due to a sense of incompetency, and partly from a feeling that the time is scarcely ripe for a satisfactory presentation of the subject; and yet there are signs which make one hopeful; and it would not be rash to predict that the knowledge twenty-five years hence will be as much in advance of to-day as our information on the subject is of the time when Dr. Kirkes made his memorable investigations. A serious difficulty exists in the circumstance that we have not to deal with a single form of disease—an entity; but rather with a special manifestation in many affections—affections, too, the pathology of which is, in most instances, by no means clear. No one can doubt that the more severe cases of endocarditis present in a typical mode all the features of those diseases which we call infective, and believe to be caused by the absorption of some poison, the development of which in the blood and tissues profoundly disturbs, and finally annihilates, function.

Briefly stated, the theory of acute endocarditis which at present prevails, and the only one to which I shall refer, is that it is in all its forms an essentially mycotic process; the local and constitutional effects being produced by the growth on the valves, and the transference to distant parts of microbes, which vary in character with the disease in which it develops. This very attractive theory can be adjusted to meet every requirement of the case, though as yet lacking certain of those substantial data so necessary for full acceptance, but which having been furnished of late years in other diseases, we may reasonably hope will in time also be forthcoming for this.

Let us see, first, what has been done, and how far the facts at our disposal seem favourable to this view. The constant presence of micro-organisms seems undoubted; only, in the simple acute form, we need more careful observations with our improved methods. Some good observers have not been able to find them;[14] others declare them to be invariable constituents of the verrucose outgrowths.[15] The careful application of such a satisfactory mode of staining as recommended by Gramm should readily determine this question. A study of the endocarditis of puerperal and traumatic pyæmia will be most likely to yield important information, as here the conditions are simpler, and the relation of the micro-organisms can more readily be determined. The cardiac complication in these cases is only part of a general process, excited by a local lesion, and is entirely secondary and subsidiary. Micrococci arranged in chaplets are constant constituents of the vegetations, and, in the case of puerperal fever, they have a close resemblance to those found in the peritoneal exudation. The well-known observations of Koch, Ogston, and others have shown the relation of microbes to pyæmia; and the recent culture experiments of Rosenbach[16] go far towards demonstration for man what Koch had previously done in the case of the pyæmia of the mouse. In these cases, a study of the modes of growth of the micrococci of the endocarditis, and of the effects of inoculations, and a comparison of these with similar observations in the organisms of the original lesion, or of the metastatic foci, should yield results of great value in the interpretation of the phenomena of secondary endocarditis.

In rheumatic fever we are still too far from any accurate knowledge of its intimate pathology to dwell on the possible connexion of any organism peculiar to it, and the endocarditis so common in its course. Klebs[17] distinguishes the microbes occurring in rheumatic cases from those of the septic forms.

In pneumonia, micrococci undoubtedly abound in the exudation of the air cells, and their mode of growth in gelatine is peculiar, but the numerous experiments on artificial production are not yet conclusive. The evidence is accumulating which places pneumonia among the infective disorders, and it certainly is a seductive view to take of its pathology to regard the local pulmonary lesion as excited by the growth of micrococci in the air cells, and the various consecutive inflammations—the endocarditis and pericarditis, the pleurisy, the meningitis, the membranous gastritis or colitis—as due to the penetration of the organisms to deeper parts, and their local development under conditions dependent on the state of the tissues. The processes are all of the character described as croupous, and have as a common feature the presence of micrococci in a coagulable exudation. We have still, however, to settle the identity of the organisms of the air cells with those of the consecutive inflammations, but we may reasonably hope ere long to have some positive data from investigations in this disease which, more than any other, offers favourable opportunities for the solution of these problems.

In diphtheria, as we have seen, mycotic endocarditis rarely occurs, and, in the few instances observed in association with scarlatina, variola, erysipelas, and other affections, we lack positive information with regard to the characters of the micro-organisms.

In the way of experimental investigation of the properties of the micrococci, not much has been done of a satisfactory nature. Heiberg[18] placed bits of vegetations from a puerperal case beneath the skin and in the peritoneal cavity of a rabbit without effect. Eberth,[19] Birch-Hirschfeld[20] have produced panophthalmos in the rabbit by inoculating the cornea; and I was able to produce well-marked mycotic keratitis in the same animals with fresh material from the valves of two cases. H. Young of Manchester inoculated rabbits with pus from an abscess in ulcerative endocarditis, and was able to detect micrococci in the blood.

No conclusive culture experiments have yet been made. Graucher[21] has cultivated a microbe from the blood, taken during life with all necessary precautions, but apparently not in series, and no inoculations of animals were made. Cornil[22] has made cultures on gelatine, but apparently no special results have been reached.

How do the micrococci reach the valves? In cases of puerperal and traumatic septicæmia the external lesion is undoubtedly the source of infection, which is conveyed through the venous system, and in these cases it will be remembered that the right heart is most often affected. In other instances, where the skin is unbroken, we must suppose them to gain access by the lungs or intestines, most probably the former; and in these instances the left heart is the chief seat of the mycosis. Whether they reach the valves with the general blood current, as Klebs supposes, or through the coronary arteries, as Köster holds, cannot be considered settled; but, from the position of the early vegetations in a non-vascular region of the valves, and from the fact already referred to that colonies of micrococci can be seen directly upon the endocardium, it seems probable that Klebs's view is the correct one. He suggests, in explanation of the fact that the lines of closure of the valves are the usual seat of the process, that the micrococci, circulating with the blood, are here closely pressed into the endothelium by the firm apposition of the flaps. Whether or not in any given case endocarditis will arise, depends greatly on the condition of the valve tissue. In a case of pneumonia or other disease, such as pyæmia, in which we may suppose microbes circulating in the blood, the endothelium of normal valves may be able to resist their invasion, or even if they do lodge and penetrate, the conditions may not be favourable for their growth; but where an individual is

debilitated and the tissue tone lowered, or if, as so often seems the case, the valves are diseased, then the micrococci find a suitable nidus, and excite, by their growth, an endocarditis which may be of a malignant type. As Dr. Goodhart suggests,[23] patients with chronic sclerotic valves are walking mushroom beds, in common times without spawn, but in periods of epidemics germs enter by various channels, which fertilise in these cases into ulcerative endocarditis; in others, to suppurative processes. Certainly, on paper, so to speak, the view which I have thus imperfectly and hurriedly discussed seems plausible enough, and meets the requirements of the case fairly well; but let us, in conclusion, follow an important rule too much neglected, and get a definite outline for our ignorance. In the first place, we do not yet know, with sufficient accuracy, the frequency of the occurrence of microbes in simple endocarditis. Are they constantly present or only in forms associated with special diseases? Secondly, we want full information of the various forms of micro-organisms occurring in secondary endocarditis, and of their relation to the microbes assumed to be the cause of the primary disease. And, thirdly, we are only at the threshold of inquiries relating to the culture of these organisms, to the macroscopic characters of their growth, and to the possible experimental production of endocarditis.

I cannot conclude without thanking my late colleagues at the Montreal General Hospital, by whose kindness I have had command, not only of the pathological, but also of much of the clinical material upon which these lectures were based. And, lastly, Sir, you will allow me to express my sincere regret that my efforts have not been more worthy of such an intensely interesting subject, and of the distinguished audience which I have had the honour of addressing.

Croonian Lectures

ON THE

HYGIENIC AND CLIMATIC TREATMENT OF CHRONIC PULMONARY PHTHISIS.

Delivered at the Royal College of Physicians,

BY HERMANN WEBER, M.D.,
PHYSICIAN TO THE GERMAN HOSPITAL.

LECTURE I.

(*Concluded from page 466.*)

THERE is a species of constitution which does not fight well when attacked by any serious disease, and especially by phthisis. I cannot satisfactorily define this complication of anatomical and physiological peculiarities of cells and tissues and nerve functions, which our old physicians, especially in Germany, used to call *erethic constitution*. A slight injury or a slight cause of irritation produces constitutional effects, especially pyrexia, quite out of proportion, and the effects do not readily disappear. The equilibrium of health is not easily regained. The pulse is generally rapid, the appetite varying, the mucous membrane irritable, and sleep imperfect. This constitution is always associated with a certain degree of asthenia, sometimes patent, sometimes masked. For the sake of shortness, we might, I think, use this term when referring to the constitutional peculiarities just mentioned. The general treatment, and especially the climates most useful to other consumptive patients, are not easily adapted to this constitution. The prognosis of the developed disease is bad. Prophylactic treatment is imperative.

A most important point in the prognosis is the degree of intelligence and judiciousness of the patient, and in many instances of the patient's friends. The delicate or sick persons who have an insight into their own condition, in the wider sense of the word, and into those influences which act beneficially on them and those which are injurious, have a better chance of recovery than those who are less intelligent, who do not see the bearing on health of all the numerous items of daily life, most trivial in appearance, but all-powerful in their accumulated action. A circumstance of almost equal importance is the *possession of means* to carry out the most suitable treatment. No other disease demands so many and such long-continued sacrifices as phthisis, and those who are able to make them have, as a rule, a greater chance of recovery than those who are not. The poor deserve our greatest sympathy. While in the majority of other diseases the ordinary hospitals place the poor almost under the same favourable conditions as the rich at their homes, this is by no means the case with phthisis; on the contrary, the majority of general hospitals are very ill adapted, and the well-arranged special hospitals for the treatment of consumption have accommodation only for one sufferer in a thousand. I wish, gentlemen, I could not only induce you to see this in the same light that I do, but also to use your influence with the public gradually to fill up this great gap in our philanthropic institutions.

Preventive treatment.—In discussing the treatment of phthisis it is impossible to restrict ourselves to that of the developed disease, and to pass over the prophylactic or preventive treatment. The latter is, indeed, in many cases, all that gives us any chance, for in some constitutions the disease once established runs a rapid course to the end, or at best cripples the patient for life; and many of those endowed with better constitutions do not possess the means to submit to treatment which often must be extended over many years. The question of preventive treatment has been ably discussed by many authors—Drs. Mac Cormac, Pollock, Jaccoud, Ruhle, amongst others; and quite lately in a comprehensive way by Ewald in his address to the International Medical Congress at Copenhagen. Some of the questions relating to the prevention of phthisis ought to belong to public hygiene and State medicine for instance, whether to destroy cows affected with tuberculosis, whether to permit the flesh and milk of such animals to be consumed; the hygienic arrangements in school-board schools, the playgrounds connected with them and the superintendence of the games, the number of school hours; the condition of factories and the work at factories, the buildings for the accommodation of working people and their families, the barracks, &c.

The questions of infectiousness and communicability of phthisis are not yet sufficiently settled to lay down prophylactic rules with regard to them, but they ought to be carefully and calmly investigated in all their bearings. I have only to deal with them in the preventive sense, not as etiological questions, but both cannot be quite separated. Dr. Andrew has fully discussed them in his Lumleian Lectures, and though we may not in all points agree with him, his reasoning, based on historical data and personal experience, deserves thoughtful examination. There is in Dr. Andrew's discussion no sign of a feeling which is so apt to intrude itself unconsciously on the inquirer, and sometimes to influence his judgment. I have, for instance, heard from intelligent men the view that it would be cruel to shun the consumptive, who is already much afflicted, to check the intimate intercourse between him and his nearest and dearest friends, or to render his condition intolerable and promote the fatal termination of his disease by not allowing him to marry. If we could think that by allowing intimate intercourse and marriage the disease could not be spread, it would certainly be cruel to give pain, but if experience and investigation should teach the opposite, then judgment ought to have precedence before feeling.

We are, I suppose, all convinced that infection can take place by inoculation, and this may possibly occur more frequently than is thought. Several instances are recorded; I remember just now two occurrences. The first is related in a communication by Dr. Lindmann in the *Deutsch. Med. Woch.*, 1883; two children who were circumcised by a man, who was in the last stage of consumption, and who, after circumcision, sucked the prepuce according to the Jewish rites, became both infected with ulcers on the prepuce and swelling of the inguinal glands, and the ulcers had the appearance of tuberculous ulcers. One of the children recovered after some months. In the other the glands became ulcerated, and caseated masses were removed from them. The child then apparently recovered, but in the third year it perished from Pott's disease and rapid phthisis. The second occurrence is recorded in the *Berlin. Med. Woch.* of 1878. The midwifery practice in the small village of Neuenburg was pretty closely divided between two midwives. One

of the two became consumptive in 1874, and died in July, 1876. Ten children without hereditary predisposition, attended by this midwife between April, 1875, and May, 1876, died within the first seventeen months of their lives; while none of those died who were attended by the other midwife, and while tubercular meningitis is a rare disease at Neuenburg. The consumptive midwife was in the habit of sucking the mucus from the mouth of the new-born children and blowing air into the mouth when there was the slightest sign of asphyxia. In this occurrence it is perhaps doubtful whether it ought to be explained by inoculation, or by contagion in the more ordinary sense of the word. It is not impossible that more cases of inoculation will be observed when once general attention is directed to this point. I remember two cases which I am now inclined to explain in this way, though at the time of their occurrence I had not done so. The first was in a wet-nurse who nursed a consumptive child; she first had an ulcer at the side of the tongue, which was regarded as due to a rough tooth, which however did not heal after the tooth had been filed, and was not cured by borax and other local applications. Several months later she lost her voice, and ultimately died from phthisis. I am inclined to think that a slight sore on the tongue had been inoculated and formed the starting-point of phthisis in this woman, who was free from hereditary disposition. The second recollection relates to a mother who nursed a consumptive daughter, fifteen years old, with whom she shared the same bed and whom she constantly kissed. She, likewise, had first a sore on the tongue and afterwards on one of the tonsils before she manifested any signs of pulmonary consumption. But in this case the mother belonged to a somewhat tainted family, and her husband had died from phthisis; although she had been apparently quite well before she nursed her daughter, yet she may have had latent phthisis before the sores on the tongue and tonsil made their appearance.

On the question of contagiousness of phthisis, the views of medical men will probably remain divided for a long time to come. The facts brought forward by Drs. Theodore Williams, Pollock, and Andrew are very encouraging, and we may be sure that phthisis is not in the same way communicable as scarlet fever and small-pox are. But we must bear in mind that there is more intimate intercourse between husband and wife, and near relatives sleeping in the same room, and even the same bed with consumptive persons, than between nurses or doctors and patients, and that, besides, the hygienic arrangements at the Brompton Hospital and at some of the best general hospitals are much better than those of many small private houses. Since I read a paper on the Communicability of Phthisis between Husband and Wife at the Clinical Society more than ten years ago, I have not met in my own practice with any such striking cases as those which I then related, so that I am happy to think that they are rarer than it seemed to me at that time; but I remain convinced, from clinical facts, of the communicability of phthisis under certain circumstances, and the experimental researches of Tappeiner, Veraguth, and Schäffer ought not to be forgotten. In preventive medicine, therefore, the infectious character of phthisis ought to lead to certain precautions, of which I can mention only the most salient. Persons affected with consumption, for instance, especially the subacute forms, ought not to be allowed to perform offices by which breath, saliva, or sputa are brought into close contact with healthy, and still less with very young or weak and diseased, people or persons with an acquired or inherited predisposition. Not without reason physicians have forbidden kissing between consumptive patients and other persons; but this prohibition recalls to my mind a beautiful German poem by Scheffel, in which a famous tom-cat, a prince of cats, watches from his throne on the roof the doings of mankind, and soliloquises on that trait of human beings, to kiss one another, especially in the time of youth. From this poetical cat's cogitation I infer that kissing is a part of man's nature, and nature, I fear, cannot be stopped.

The secretions and excretions of consumptive persons, and the wearing apparel, bedding, &c., soiled by them, especially the expectoration, should be disinfected and carefully removed. Woollen articles of furniture ought also to be avoided or frequently changed for disinfection. No dust ought to be made in sick rooms or wards, as the microbes are likely to be moved about in this way. The cleaning of rooms and furniture by a dry process of sweeping and dusting ought therefore to be forbidden. Ventilation of the sick room ought to be most abundant, not only for the sake of the sick persons themselves, but for those in contact with them, and the latter ought to be much in the open air and attend to their health by all other means, in order to keep up there power of resistance.

It is our duty to prevent as far as lies in our power the marriage of consumptive persons, and even of persons who though not actually consumptive themselves belong to families with a strong consumptive taint. We must at all events endeavour to convince those with whom we come into professional contact of the importance of this duty, but notwithstanding all this, our advice will often be disregarded, and those who know the meaning of the wonderful word "love" and its equivalent in other languages cannot be astonished at it.

Failing in the prevention of marriages, we must direct our attention to the management of those affected with *hereditary tendency*. The infants of consumptive mothers ought never to be suckled by the latter, but ought to have perfectly healthy wet-nurses, or if this be impossible, they ought to live on milk from sound cows, or donkeys, or goats during the first year—boiled if there is the slightest cause for suspicion as to purity; and milk ought to form during the first six years the principal article of food, and ought only gradually to be in part substituted by other animal food with an admixture of farinaceous and green vegetables. I quite agree with Dr. Duckworth's remarks in the *Practitioner* on the insufficient use of milk as an article of diet in England, with regard to children as well as adults; and these remarks would be still more applicable to other countries. Those who have been in the country districts of Italy know how difficult it is to obtain milk. The child ought never to sleep in the same room, and still less, in the same bed with the consumptive parent or any other consumptive person. The child's room ought to be large, with plenty of light, in a southern or south-western aspect, with abundant ventilation by day and by night. Whatever we may think of Dr. Henry Mac Cormac's explanation of the origin of consumption by the "breath rebreathed," it must be acknowledged that pure air is the best means to prevent consumption; that he has pleaded in favour of it in a more eloquent way than any other author, and that his teachings ought to be accepted much more universally than has hitherto been the case. The temperature of the room ought not to be too high, 65° F. being quite sufficient for the very young, and 62° for somewhat older children, and less in the sleeping-room. The skin ought always to be covered with flannel, the clothing warm and loose; there should be daily sponging with gentle friction. The temperature of the water used is to be gradually lowered, 60° F. being sufficient after the second year. The child ought to be taken out into the open air for several hours every day, and later on to spend the greater part of the day in the open air. If it can be arranged, the house ought to be in the country, on a dry slope with sunny aspect. Active exercises ought to be encouraged at an early period, and to be gradually increased as to duration and activity of movement—games, gymnastics, rowing, riding on horseback, climbing, and all kinds of exercises by which the muscles and the organs of circulation and respiration are brought into play, and as a consequence the nutrition of the body improved. Mental education need not be neglected, but ought to go on, and can go hand in hand, with sound physical education; but confined rooms and sedentary habits ought to be rigorously avoided. No trade or profession ought to be permitted which induces such habits, or which exposes the delicate person to dust or tainted air, but farming, seafaring, and other open air occupations ought to be selected. The period of cessation of growth, and the first year succeeding it, require special attention. But how can this be applied to the children of the poor? I am afraid that I must say that this is one of the problems not yet solved, and perhaps not to be solved in the very near future. Let us at all events lay down these principles for the guidance of those who have influence on the nursing and education of the children of the poor; and some improvement we may hope will gradually be achieved, and is often achieved already now in individual cases and in well-arranged orphan asylums. With regard to schools, too, we can demand the best hygienic arrangements, and playgrounds attached to them, and gymnasia, and drilling masters.

Every one of us has, I suppose, met with instances which prove how much can be done by judicious physical education, even under apparently hopeless circumstances; yet you will

pardon me, I hope, gentlemen, if I relate to you the outlines of a very instructive family history. About thirty years ago I saw a lady affected with rapid consumption, living in a small street near Bloomsbury-square; the husband, a teacher of languages, had just died under my care at the German Hospital of chronic consumption, at the age of thirty-eight. He was a member of a consumptive family. The wife's family too was by no means free from consumption; indeed, out of three brothers and two sisters, two brothers and one sister had already died of the disease. She herself had had seven children, ranging from twelve years to one year of age. The second of these had died from tubercular meningitis. The others—namely, four boys, of twelve, nine, seven, and two years, and two girls of five and one—were fairly healthy, excepting the youngest boy, who was pale and rachitic. After the death of the mother some relatives, intelligent and wealthy at the same time, took entire charge of the children. They took them to their home in a mountainous district of Silesia, one of the healthiest parts of Germany, and brought them up on the plan which I have just sketched. The oldest son remained well as long as he took much outdoor exercise, but at the age of twenty-three he became absorbed in the study of the origin and affinities of languages, worked day and night, gave up exercise, took most of his meals in his study surrounded by books, and perished from rapid consumption in less than eighteen months. The second son took to farming, and was in excellent health up to the age of twenty-nine, when he found his occupation not remunerative enough, and began to work in a commercial house, being confined to an ill-ventilated office during the greater part of the day, and working, besides this, at home with the hope of gaining a better position. After scarcely two years of this intensified city work he had several attacks of hæmoptysis, and died in less than two years from the outset. The third son has become a cavalry soldier, leading a judicious life, and is a strong and healthy-looking man. The fourth child, then a girl of five years old, is now a country parson's wife in a healthy part of Silesia, has no children, and is perfectly healthy. The youngest son, rachitic as a child, has become a powerful man, and is a farmer near Manitoba in Canada; and the youngest daughter staying with him is likewise strong and healthy.

The history of this family is very instructive. It shows that by favourable circumstances, even a strongly marked family tendency may be neutralised; and this becomes still more manifest when I add that by far the majority—viz., nine out of eleven—of the cousins of these children have died from consumption before the age of twenty-eight. It further teaches the serious lesson, that if the stringent rules of health are neglected even after the constitution has become satisfactorily developed, the disease may suddenly show itself and run a rapid course. My experience, indeed, forces me to say that a strong hereditary tendency, especially from the mother's family, requires the strictest attention, not only during the first thirty years, but from infancy to old age, for old age does not shelter from phthisis. I have notes of several cases where with a healthy mode of living the health had been perfect up to fifty, and phthisis was developed afterwards under unhygienic influences. Thus, for instance, C. M——, with a consumptive history on the mother's side, was perfectly well as a sailor up to the age of fifty-two, when on account of a chronic and fatal disease of his wife he retired from the service, and while nursing her was much confined to the house for many months. Dyspepsia and phthisis developed themselves, and he died at the age of fifty-six. A. D——, likewise with consumptive tendency from the mother, enjoyed good health as a traveller for a commercial house, till at the age of fifty-four he exchanged this occupation for office work as a partner in the house and lived altogether in town. His health began to fail after a year, and he died before he was fifty-nine. I could mention other similar instances, and have also had the opportunity of seeing repeatedly "consumption" as the certified cause of death in life insurance cases after sixty, where insurance had been effected late in life, in spite of hereditary disposition, because it had been thought that at so advanced an age the office might be secure with regard to the development of consumption. But I am convinced that where the hereditary predisposition is much marked there is only that "security" of which the great poet says:

> "And you all know security
> Is mortal's chiefest enemy."

Altogether there seems to be no good foundation for the general impression that consumption is rare in the later part of life. Dr. Somerbrodt found in twenty-five post-mortem examinations of military pensioners eleven times tubercular lesions as the cause of death, the average age at the time of death being eighty-two. Dr. Würtzburg found that in the Prussian monarchy, on comparing the number of deaths at certain ages from consumption with the number of persons of the same age living, phthisis is decidedly a more frequent cause of death among the old than among the young. Thus he gives amongst 10,000 persons living: ninety-three deaths from phthisis in the period of age from sixty to seventy; nearly sixty-eight from fifty to sixty; only forty-one from thirty to forty; only thirty from twenty to twenty-five. At Copenhagen likewise, according to Lehmann, the death-rate from phthisis to the number of persons living at the same age increases with advancing years up to the age of seventy-five. There is, however, in this respect a difference between different countries; and in England and France, for instance, the death-rate is greatest between fifteen and thirty-five. It is not easy to say what is the cause of this difference; it may be partly due to a difference in the names given to the diseases in the different countries; thus in England the number of deaths from "lung disease" in old age is proportionately greater than in Prussia, while that of "phthisis" in old age is smaller. It is possible that some cases which in England are certified as "chronic bronchitis" or other "lung disease" would receive in Prussia the name of phthisis. But part of the difference may be accounted for by the fact that during the much colder winters in Prussia old people are more confined to narrow, ill ventilated, stove-heated rooms than is the case in England, where the cold is never great, and where open fireplaces do not allow the air to be vitiated to the same degree.

The preventive treatment of the *acquired predisposition* to phthisis is similar in principle to that of the hereditary predisposition, though generally it is not required for the whole of life, but only for a shorter or longer period, excepting in those cases where, by deterioration of the health of the parents during the period preceding fecundation, or of the mother during pregnancy, or by unfavourable influences during the first periods of extra-uterine life, permanent weakness or insufficiency has been created. The preventive treatment must be varied according to the constitution and the circumstances of the individual, the causes which have produced the predisposition, and the system or part of the body principally weakened. You will not wish me to enter into details, but allow me briefly to discuss a few points only. A fruitful source of phthisis is the *tendency to catarrh of the respiratory mucous membrane*. It is not to be treated by confinement to hot rooms and by avoiding the open air; but, on the contrary, by hardening and by accustoming the delicate person, clothed in flannel, but not loaded with clothes, to constant exposure to the air in almost all weathers—walking, driving, riding in open carriages; by abundant though judicious ventilation of the rooms; by regular sponging of the skin—at first tepid, perhaps with vinegar, afterwards cold—and by friction; by strengthening the whole system by nutritious food and by frequent prolonged changes to the seaside or the mountains, according to the nature of the constitution. These frequently recurring catarrhal affections may form predisposing causes in different ways, especially by producing sore places in the mucous membrane and thus allowing the bacillus to settle; or by weakening the epithelial cells of the mucous membrane and their ciliary action, or by causing imperfect breathing from unconsciously avoiding deep inspirations in order to avoid coughing, or by weakening the nutrition and energy of the whole system. The latter element is powerful, and by no means rare. Many persons remain excessively weak for a long time after a so-called "severe cold," and lose entirely their appetite and their inclination to exercise and to work.

The tendency to imperfect breathing which often accompanies protracted colds is best remedied by judicious exercise, even if it causes at first fatigue. Persons presenting the imperfect development of the thorax, often described as the "paralytic form," and the general appearance known by the term "phthisical habitus," whether hereditary or acquired, demand similar management, as those subject to constant catarrhs. The imperfect development of the thorax especially requires pulmonary gymnastics, deep inspirations, alternating with complete expirations, breathing with raised arms in order to allow free entrance of air into the apex, judicious climbing of hills and mountains. It is not only our duty to remove the acquired disposition, but also to prevent the acquirement of it by physical education,

general hygiene, and by the management of acute diseases, especially those which affect the respiratory organs, as measles, whooping-cough, diphtheria, bronchitis, pneumonia. The broad rules laid down by Dr. Wilson Fox, in his article on Pneumonia in Dr. Russell Reynolds's "System of Medicine," relieve me of the duty of further entering on this subject. But with regard to measles, diphtheria, and whooping-cough, I cannot help pointing out the injurious influence of hot rooms and fear of ventilation, to which I have been repeatedly obliged to ascribe a share in the cause of phthisis. Change of air to mild seaside or fairly bracing inland places is often important during the convalescence from these diseases, but the fatigue of long journeys is to be avoided.

Preventive medicine has a very large field in the subject of phthisis. I need only remind you of the change in the phthisis mortality of soldiers and prisoners by improved ventilation in barracks and prisons, and we must always have before our minds the important discovery of Bowditch and Buchanan, that drying of the soil by drainage diminishes the mortality from phthisis. The practical application requires no words.

SOME BRIEF NOTES ON THE LATE OUTBREAK OF CHOLERA IN PARIS.[1]

BY HY. TOMKINS, M.D., B.Sc., &c.,
RESIDENT MEDICAL OFFICER, MONSALL FEVER HOSPITAL, MANCHESTER.

THE outbreak of cholera in Paris during last November afforded an opportunity for those interested in epidemic diseases of seeing and studying this scourge of Eastern countries; and at the end of the month I visited Paris for that purpose, though at that time the outbreak had begun to subside almost as rapidly as it commenced, so that in all I saw only some forty to fifty cases. The history of its appearance and progress in Europe last year may be summed up in a very few words. In the middle of June the first cases were reported in Southern France from Toulon, and the following week cases were occurring in Marseilles, and quickly assumed serious proportions. As it subsided in the south of France it spread to the northern parts of Italy, and early in September Naples had become attacked with what proved to be a most virulent outbreak, the densely crowded and filthy quarters of that fair city affording congenial soil for the spread of the disease, with the result of a loss of some 11,500 lives. At this time it had disappeared from the towns in the south of France, but towards the end of October cases occurred at Yport, a small fishing village, described as filthy and dirty in the extreme, situate upon the coast of Normandy; then, after a few cases had been heard of in one or two places in Northern France, the startling official notification of its presence in Paris appeared on Nov. 5th, though it would seem that several cases had previously occurred in the capital, but were kept quiet for fear of creating a panic in the public mind; the cases increased rapidly in number daily, and on the 11th of that month 152 new cases were reported with fifty-six deaths.

The first cases occurred amongst the inhabitants of the east-end of Paris, in a dirty, filthy neighbourhood off the Faubourg St. Antoine, situate in the eleventh arrondissement, a district lying beyond the Place de Bastille; and to those familiar with this quarter, it will be admitted that for filth and degradation, both morally and physically, it is perhaps worse than anything to be found in the east-end slums of London. From the 4th to the 17th 1250 known cases had occurred, with 617 deaths, and by this time only one of the twenty arrondissements into which Paris is divided was free from cholera. During the last week in November the disease rapidly declined, and in the second week of December it was practically at an end, the cessation having been as sudden as its onset. It is difficult, in the absence in Paris of compulsory notification of infectious diseases, to state with exactitude the total number of attacks, but it was probably not less than 2000, as 900 deaths occurred, and amongst the cases treated in hospital, which were about 1000, there were more than 500 deaths, or a mortality of over 50 per cent.; but the mortality amongst these would certainly be higher than amongst those not treated in hospital. As has happened so often in the past in the history of epidemics, when the cholera reached Paris it was ill-prepared as regards hospital accommodation and general organisation for the removal of patients, disinfecting of infected dwellings, and the like. It was at first intended to use only one or two hospitals situate on the north and south of the city, but it was soon found that in face of the sudden and severe collapse, so common in cholera patients, they ran great risk of dying, and actually died, in transit from their homes to hospitals at a distance therefrom, and wards were set apart in the general hospitals situate in various parts of the city; thus, the St. Louis, Tenon, St. Antoine, Lariboisière, Cochin, and other hospitals, all received cholera patients.

At the time of the outbreak the regular ambulance service of Paris consisted of only some half dozen conveyances, which were totally inadequate for the demands made upon them, and ordinary coaches had to be pressed into the service. Immediate steps were, however, taken by the health authorities, and by the time the epidemic was declining an efficient service of forty ambulance carriages was in operation, together with a corps of disinfectors, ready at once to proceed to any house where cholera was reported to be present. In the matter of ambulances we here might with advantage take a lesson from Paris. Instead of being built as ours are of a most pronounced and distinctive, not to say funereal-looking pattern, so that everyone at a glance recognises "the fever van," they are constructed externally to resemble the ordinary coach for hire in the streets, and thus avoid observation to a very large extent. At the Health Exhibition last year there was exhibited an ambulance, built for the London Fever Hospital, which, to all outward appearance, was a handsome brougham carriage of large size, whilst inside it was fitted in every way as comfortably for the patient as could possibly be desired.

All the hospitals in Paris, as is probably well known, are supported out of the rates, and managed and controlled by the governing authorities, there being no hospitals supported by voluntary contributions, and they are under the immediate direction of the Administration de l'Assistance Publique. The routine with regard to cholera cases was as follows. On a cholera case occurring information was at once taken to the nearest police station, which is in telegraphic communication with the central Bureau de l'Assistance Publique, situate near the Hôtel de Ville; here it was decided to which hospital the case should be sent, instructions telegraphed to the nearest ambulance station for its removal, and some of the staff of disinfectors at once sent to disinfect the patient's rooms.

The hospitals visited by me were the Cochin, the St. Antoine, the St. Louis, and the Mariniers. At La Salpétrière, though not a hospital in the ordinary sense of the word, several cases occurred amongst the inmates, and Dr. Charcot informed me that the first case they had there was in an old woman who had not been out of the building for four years, and not even a guess could be given as to its origin.

At the Hôpital Cochin, the cholera patients were treated in wooden structures of which this hospital has many to supplement the accommodation in the ordinary wards. The patients were under the care of Dr. Beaumetz, who courteously afforded me much information and help. In these wards trial was made of saturating the air with ozone. The apparatus employed had previously been in use at Toulon, and consisted of a large air-pump which forced the air through a solution, the composition of which I was not able to ascertain, but which saturated the atmosphere passed through it with ozone, as shown by pieces of paper moistened with iodide of potassium and starch placed in various parts of the wards being rapidly changed in colour and darkened. There was used also in these wards, a new remedy, Erigereon Canadensis, an American drug much lauded for its astringent properties in checking diarrhœa and dysentery. It appeared to check the purging when given, but in many of the cases here purging was very slight and not the most prominent symptom. The general results of these measures do not appear to have been of a very encouraging nature, as 50 per cent. of the cases proved fatal.

At the Hôpital St. Antoine, situate in the district above alluded to as being the locality where the first cholera cases appeared (and which received the largest number of any single hospital in Paris), transfusion was much practised by Professor Hayem, who had had made a very simple and easily managed apparatus for this purpose. The solution used was the ordinary one of common salt with a small pro-

[1] A paper read before the Manchester Medical Society, Feb. 4th, 1885.

portion of sulphate of soda, and it was had recourse to not only in the worst cases, but also in those of a less severe type, and a considerable number of those thus treated recovered. Usually the injection was made into one of the veins at the bend of the elbow, but in some cases the internal saphenous vein in front of the inner ankle was selected. The immediate effect of that treatment was often for a time most marked and beneficial, appearing to give the patient temporarily new life, but as a general result of the treatment here the mortality also reached 50 per cent. Should I ever have to treat cholera myself, I should certainly be inclined to give transfusion a trial in bad cases, as it without doubt in many instances helps to prolong life where it does not actually succeed in saving it.

It was at the Hôpital Mariniers, situate near the fortifications to the south-west of Paris, that the most perfect arrangements, from a sanitary point of view, had been put into operation. This was a new hospital, scarcely finished at the time of the outbreak, and was erected for the purpose of an infectious hospital, and presents some interesting features in hospital construction. It has accommodation for 300 patients, and was built in about six weeks. The wards are all one-storeyed only, and are raised upon wooden piers above the ground, so that the air circulates below as well as above and around them. It was built in a skeleton frame-work of wood, this being brought to the site ready to put together, and the spaces were then filled in with brick-work, consisting of only one brick in thickness placed end to end, so that the walls are only some four inches thick. Externally they present a neat and substantial appearance. On the inside the walls were finished off with plaster, and had a much more comfortable appearance than the usual temporary wooden erections, and gave none of the difficulties in maintaining an equable and proper temperature met with in these latter. The arrangements for disinfecting everything connected with the wards, &c., was most complete. A large gas stove, on the same principle as the Ransome (Nottingham) disinfecting stove, had been constructed. A special room for fumigating with sulphurous acid fumes was built, and still further machinery was erected of a very simple but apparently efficient character for disinfecting all the waste water, slops, and sewage before leaving the hospital sewers. At the extremity of the grounds a large tank was constructed in the earth, into which all the hospital sewers opened; adjacent to this was erected a strongly made iron cylinder and a large steam boiler. The sewage was drawn into the cylinder and then subjected to a temperature of over 300° by steam forced into it from the boiler before being discharged into the sewers of the town, a temperature probably sufficient to kill all forms of germ life. The working of this was most simple, and necessitated the attendance of only one man, and was in operation day and night. In the wards themselves all infective material—stools, vomit, urine, soiled linen, &c.—were at once treated with chloride of zinc, and this appears to have been the practice followed at most of the other hospitals, chloride of zinc being apparently the disinfectant most in vogue in Paris. For the disinfection of rooms, houses, and conveyances sulphurous acid was used. The treatment adopted at the Hôpital Mariniers was not of a very special character; opium in the form of paregoric and wine was much used, the limbs rubbed with a turpentine liniment, and hot air baths also given, these two latter remedies appeared to give much relief to the muscular cramps. The mortality here and elsewhere was 50 per cent. The bodies of those who died were covered with sawdust saturated with chloride of zinc, and buried in a few hours.

As one who saw cholera patients for the first time, what struck me with most force was the great fear which seemed to lay hold of many of these patients, so unlike anything met with in the ordinary zymotics—such as small-pox, typhus, diphtheria, and the like. The sudden and extreme collapse, the comparative absence of real delirium, and as the later stages come on the shrunken features, the shrunken eyeball, dark areola round orbit, and the shrivelled, inelastic condition of the skin, so that when pinched and raised up it showed scarcely any elasticity or tendency to retract itself in the normal manner. In one man at the Hôpital Cochin this inelastic state was marked even in the convalescent stage. After seeing patients in the collapse of cholera it is easy to understand how it has been possible to mistake patients really alive for dead, so like is the condition to that of a corpse. After death this shrunken, livid appearance is perhaps as characteristic of the disease as any of the anatomical lesions met with, these latter being quite as vague and indefinite as those of typhus, and in the absence of any ante-mortem history it would, I think, be difficult to diagnosis a case of cholera from a post-mortem examination alone. There were usually more or less inflammatory changes in the mucous membrane of the intestinal canal, but these varied much in degree; other lesions described were equivocal and doubtful in the cases which came under my notice.

Any remarks upon cholera at the present day without an allusion to the comma bacillus would indeed be the play of "Hamlet" with Hamlet left out; but as a matter of fact, when brought face to face with the treatment and management of the disease, the bacillus has no *locus standi* either as regards treatment or hygienic measures. Whatever may be the ultimate outcome of Koch's discovery, at present it is like the bulk of the work of the physiologist and biologist—interesting chiefly in the laboratory, though none the less great and important results may, and probably will, flow therefrom to practical medicine and treatment of disease. Few of the physicians in Paris (amongst the exceptions notably Dr. Strauss) appeared to trouble themselves much about the bacilli, and in some of the wards but little attempt was made even to find them. Koch describes them as easily found by staining in the ordinary manner; but although I have searched since my return, and have had also the assistance of Dr. Dreschfeld, I have up to the present time not been able to find one, to my mind, respectable comma bacillus in either stools or intestine, though ordinary putrefactive bacilli are to be found in abundance. The further knowledge we have gained respecting cholera from the outbreak in Paris and Europe generally last year has been but little; it did not need this to teach us that filth and overcrowding and insanitary conditions generally formed its special home, or that the poor, the badly-fed, and the intemperate were its especial victims. In its treatment we have advanced nothing; of its origin, mode of spreading, its incubation, and its cause we are as much in the dark as ever. Further evidence has been gained that, given good sanitary surroundings, there is but little risk of direct infection from the sick; amongst the large number of medical men, students, nurses, and other attendants on the sick in Paris, I was not able to ascertain that a single case had occurred.

To those familiar with the cesspool arrangements in Paris, together with the suspicion as to the purity of some of its water-supply, it will appear highly probable that in the present year we shall have again opportunity of studying all and everyone of these questions, even if the disease does not reach our own shores, for spread as it was more or less throughout Paris, there must be myriads of bacilli only waiting for the coming summer and favourable conditions of growth to again break out into activity and life.

ELECTRIC ILLUMINATION OF THE VARIOUS CAVITIES OF THE HUMAN BODY, FARADISATION, GALVANO-CAUTERISATION, AND ELECTROLYSIS, BY MEANS OF POCKET ACCUMULATORS.[1]

BY FELIX SEMON, M.D., M.R.C.P. LOND.,
ASSISTANT-PHYSICIAN IN CHARGE OF THE THROAT DEPARTMENT OF ST. THOMAS'S HOSPITAL.

(*Concluded from p. 471.*)

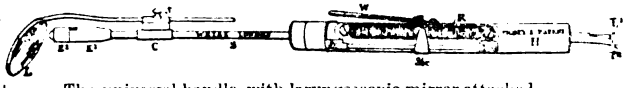
1. *Illumination.*—For illumination of the mouth, pharynx, naso-pharyngeal cavity, larynx, nose, ear, vagina, and rectum one universal instrument has been constructed. Its total length is 8¾ inches. It consists of an ebonite handle 4½ in. in length by ½ in. in diameter, attached to which at one end is a German silver stem or tube, 2¾ in. in length by ⅛ in. diameter. Fitted at the end of this tube is an ebonite socket, ½ in. long by $\frac{5}{16}$ in. diameter, inside of which are two platinum springs connected to two insulated copper wires running the whole length of the instrument to two terminals at the rear of the handle. These latter terminals are connected to a flexible silk cord, which connects the accumulator with the instrument. Fitting into the above socket

is the shank of another socket, containing a small incandescent lamp, which is secured therein by means of plaster-of-Paris. Connexion between the lamp and the platinum spring mentioned before is made by the shank being inserted and fixed by means of a bayonet joint, which, as soon as the proper position has been acquired, establishes good electrical communication. The circuit is completed when the practitioner, who holds the instrument like a penholder, depresses a small brass switch fitted on the handle for that purpose, and in such manner as not to inconvenience his grip. The lamps are only ¼ in. at the largest part, and $\frac{5}{16}$ in. in length. The electro-motor force of these accumulators and lamps has been tested by Mr. Vesey, who finds that the average of those he has tested gives about 4·25 volts, and the internal resistance about ·4 ohm. It may be mentioned that the practitioner may at a slight expense be able to estimate the electro-motor force, or working condition, of the Bunsen battery, as well as of the accumulators at any time by means of a small galvanometer. The force of the current is estimated by the amount of deflection of the needle; the greater the deflection, the better the condition of the battery and accumulators. The delicacy of the carbon filament of the lamp renders it almost impossible to manufacture them with the same amount of resistance in each, and it will be found that there exists considerable difference in this respect in individual lamps. If it be therefore stated that the average amount of resistance in the lamps is 3·8 ohms, this statement must be accepted in quite a general sense; it has in fact been found by us that sometimes lamps with too little amount of resistance will be brought beyond the point of incandescence if connected direct to a powerful and well-filled accumulator. This means practically the burning of the carbon filament and destruction of the lamp. In order to avoid such a contingency, a small resistance coil has been fitted to one side of the handle of the instrument. A small scale divided in 4 ohms or less is placed by the side of the resistance coil; the maximum amount of resistance being marked towards the rear of the handle, the minimum towards the other end, being marked 4 and 0 respectively. By simply pushing the sliding contact opposite any of the divisions the practitioner can accurately regulate the amount of light required for this purpose. It is desirable, when working with a *new* lamp, that the total amount of resistance be placed in circuit, and then altered till the point of incandescence is reached; thereby many a lamp will be saved from being spoiled.

The instrument just described, and attached to an accumulator, will be found very serviceable for the illumination of the pharynx, mouth, ear, nose, vagina, and rectum. It gives an equal, steady light, the brilliancy of which can be regulated up to about two candles power. At the same time the top of the instrument gets warm so slowly that for all practical purposes this question can be left entirely out of view. It is of course necessary not to touch moist mucous membranes with the projecting segment of the lamp, because, though the bulb is very strong glass, yet accidents may occur under such circumstances; however, by exercising ordinary care they will be entirely avoided. In case the illumination of more deeply situated cavities of the body be desired, as of the abdominal cavity after ovariotomy, or of the bladder after lithotomy, it will only be necessary to provide the instrument with a somewhat longer stem. The greatest triumph, however, will be reserved, I anticipate, for the instrument in its application to laryngoscopy and posterior rhinoscopy. It is quite true that a real, fortunately not very frequent, difficulty of the former mainly depends upon the configuration and degree of elevation of the epiglottis, but I have little hesitation in saying that a large number of beginners are already deterred from pursuing their laryngoscopic studies by the difficulty they experience in concentrating the light reflected from the frontal mirror attached to their forehead upon the laryngeal mirror held in the patient's fauces. The electric laryngoscope presently to be described does away with the whole difficulty of double reflection, and thus with the difficulties just mentioned. It is constructed at a moment's notice by the practitioner himself by simply slipping the stem of the laryngoscopic mirror into a sliding collar fixed by spring jaws to the stem of the instrument, which collar is capable of begin rotated round the stem, and thereby giving the mirror an almost universal movement, and enabling the operator to hold the instrument in the manner most convenient to himself. It has been mentioned before that the little lamp and its coverings get warm very slowly; so little indeed is the amount of heat given out, that with the electric laryngoscope it is as necessary as with the common one to warm the mirror previous to introducing it in the usual manner, in order to avoid the condensation of the expired air on the reflecting surface. It is a most important point, found by me only after very long-continued and laborious trials, that for the purpose of laryngoscopy the mirror should be pushed into close proximity to the lamp, and the latter should be just opposite its *uppermost* part, and in a line with the vertical diameter of the mirror; whilst, on the other hand, in posterior rhinoscopy the lamp should be in a line with the vertical diameter of the mirror, but this time opposite its *lowest* part. Attention to these two points is very necessary to secure good illumination of the parts in question. By following the foregoing directions, the operator will obtain a very good image of the parts with far less trouble than by the old method. (Fig. 2.)

I have now used the instrument for laryngoscopy and rhinoscopy in both hospital and private practice; and among the cases I have examined were some which may fairly be designated as test cases — cases in which the patients were in bed in the recumbent position, and unable to move; and in all these cases the electric instruments have fully answered my expectations. I have repeatedly extirpated laryngeal growths, holding the forceps in my right hand and the electric laryngoscope in my left, in the usual manner. Of course, mirrors of various sizes, and supplied with stems of the same diameter, may be inserted into the before-mentioned sliding collar, so that the practitioner will actually only require one universal handle for illuminating the different cavities. It is here the place to make an observation about the colour imparted to the structure by the electric light. Unless the full point of incandescence be reached, the light has a peculiar reddish-yellow tinge of its own, and the parts

FIG. 2.



The universal handle, with laryngoscopic mirror attached. H, Ebonite handle. S, Stem of German silver. E^1, Ebonite socket containing platinum springs. E^2, Ebonite socket containing incandescent lamp, and fixed into t^1 by means of a bayonet joint. L, Laryngoscopic mirror, attached to S by means of sliding collar (c), in which it is fixed by screw (s). W, Brass switch, by pressure upon which the circuit is completed. R, Resistance coil. *Sc*, Sliding contact for regulation of the amount of resistance. T^1, T^2, Terminals for connexion with wires leading to the accumulator.

appear more brilliantly coloured than they really are. It will be necessary to keep this in mind, and to examine a few patients, first with the ordinary daylight and then with the electric light, or *vice versâ*, in order to avoid erroneous diagnoses of "congestion of the mucous membrane."

Finally, it may be observed that when operations have to be performed within such narrow cavities as those of the nose and ear, it will be impossible to introduce the lamp—though this alone can be easily passed into the nose between the branches of a Duplay's speculum simultaneously into the nasal or aural speculum with any instrument by means of which the operation has to be performed. In order to obviate these difficulties I have borrowed from the interesting paper of Dr. Macintyre in the *Glasgow Medical Journal* of February, 1885, on the Use of the Electric Light in Medicine, the idea of having my little incandescent lamps provided with a clip easily attachable to any of the specula for examination of any cavity, and permitting the introduction of instruments through this, whilst at the same time the field of operation is sufficiently illuminated. This will be useful in cases of polypi, hypertrophy of the nasal mucous membrane, aural polypi, operations on the tympanum, &c.

2. *Faradisation.*—The electro-motor force of the accumulators can be made useful in a very simple manner for faradisation by simply attaching the leading wire from the accumulators to the terminals of a small coil as used for medical purposes. It has been found that for a small coil one accumulator is quite sufficient, and, in fact, it is not advisable to increase the number of accumulators unless the practitioner is certain that the insulation of his coil is perfect. The strength of the current can, of course, be regulated in the usual manner by the sliding tube which covers the core of the coil. The use of the accumulator for these purposes will enable the practitioner to dispense with

the ordinary box containing the bichromate battery and coil, the former of which is, according to my own experience, very apt to be out of order just when it is wanted.

3. *Galvano-cauterisation.*—A considerable advance towards the popularisation of this most valuable method will be made, I hope, by the introduction of accumulators as generators of the electric current. Hitherto it has been urged, with a certain degree of justice, that the apparatus necessary for it was very cumbersome, apt to get out of order, expensive, and capable of being used only in the practitioner's private house. A good galvano-caustic battery entails a considerable outlay, and such batteries, which are filled with bichromate of potash solution, can hardly be used at patients' homes, except in quite exceptional cases. Thus, certain minor operations, in which the galvano-caustic method is most useful—as, for example, destruction of pharyngeal granulations, removal of nasal polypi, &c.—are at this moment practically limited to the practitioners' own residences. The substitution of three or four accumulators coupled together in the same way as an ordinary battery of several cells (i.e., the *minus* pole of one and the *plus* pole of the other, and so on throughout the series, and finally connecting the two poles, which are left unoccupied, to the wires leading to the instrument) will enable the practitioner to perform in future such minor galvano-caustic operations at the patient's own residence. The combined electro-motor force of from two to four accumulators suffices to bring the platinum or steel wire used in connexion with my friend Dr. Schech's (of Munich) excellent galvano-caustic instruments up to any degree of heat, from dull-red to white. In order to regulate the degree of heat, I have requested Mr. Weiss to supply a small resistance coil of the same pattern as that used for the universal handle to the handle of Dr. Schech's écraseur and knives. I may remark that I find the accumulators get comparatively soon exhausted when heating the instruments, and that some little time elapses before the platinum points are heated. The explanation of this is that the steel wire or platinum points offer a very considerable resistance. It will therefore be necessary to be quite sure that one is in the possession of several well-charged accumulators before starting upon a galvano-caustic operation at the patient's house.

4. *Electrolysis.*—It is obvious that the electro-motor force of the accumulators can be used for electrolysis. For this purpose one accumulator will suffice, and indeed in most cases so much less current will be required than that supplied by one accumulator, that it has been deemed advisable to interpolate a small resistance into the wire between the terminals of the accumulator and the electrolytic needles used for the destruction of tumours.

I am far from believing that the apparatus just described is incapable of further improvement. Nor do I claim great originality for the idea or the adoption of the different elements of its construction for the purposes just mentioned. But I think I may claim for the apparatus that it is the first of its kind which enables the practitioner to get by a small outlay possession of a portable and trustworthy apparatus, by means of which he can more easily than formerly examine the cavities of the human body, especially the larynx and the naso-pharyngeal cavity; and perform faradisation, galvano-cauterisation, and electrolysis at the patient's own house without constantly being in the instrument maker's hands, and all at a smaller expense than was formerly involved by the purchase of a set of laryngoscopic instruments, a faradaic coil, a galvano-caustic battery, &c.

P.S.—Sooner than I anticipated one of the possibilities of further improvement bids fair to become an actuality. Mr. Vesey has informed me that a new primary battery has been invented, which possibly may supersede the accumulator altogether. This battery will be made by the Primary Battery Co., London. It is constructed in the form, and nearly in size, of one of the accumulators just described, and its peculiarities are enumerated in the following note, kindly made for me by one of the officers of the company.

NOTE ON THE PRIMARY BATTERY.

"In its ordinary form this battery offers the following advantages over the batteries in general use at the present time, such as the Bunsen, Fuller, Daniell, Leclanché, &c. It has a high and constant electro-motive force, a very low internal resistance, and is the very simplest possible form of a voltaic battery—viz., two elements (positive and negative) immersed in a simple and inexpensive fluid. The electro-motive force of each couple is two volts, and remains constant at this until the cell is nearly exhausted, or until all the work which it is calculated to do has been got out of it. In order to obtain the E.M.F. of two volts with other primary batteries it is necessary to use two different exciting fluids, one of which is contained in a porous pot. One of these fluids is usually nitric acid, which is very objectionable on account of its fumes, and is also expensive. In the new battery both the plates dip into a fluid which consists of one part by bulk of sulphuric acid to nine parts of water. The use of a porous pot in a battery also adds greatly to its resistance, and there is therefore a great gain in this direction, in being able to dispense with it. In the form in which it is now shown (small pocket form, for surgical purposes), it offers the following advantages over the secondary batteries, which up to the present time have been found the most convenient. In the first place, the fact of its being a primary battery is of great advantage, because the process of 'charging' is superseded, and the practitioner has simply to take the plates and insert them in the cover of the cell, fill the cell with the diluted acid and water, and fasten down the cover, to obtain at once a battery in full working order. When the battery is worked out the cover is removed, a fresh pair of plates and a little fresh fluid introduced, and the battery is again ready for use. In action the battery is practically the same as the accumulator already described."

I have considered it my duty to give full particulars, so far as I know them myself, of this new battery; because, if all the foregoing statements be sustained by facts, there can be little doubt that this battery will ultimately take the place of the accumulators. At the same time, it must be distinctly understood (1) that I am quite unable to bear out any of these statements by personal experience, not having had the opportunity of working with the battery at all; (2) that it is still an open question whether it will be possible to manufacture these batteries in such a form as to enable the practitioner to recharge and insert fresh plates himself, if the battery be of the sealed pattern; and (3) that the battery is not yet in the market, and I am unable to say when it will be. I shall, of course, pursue my experiments with it, and shall not fail to supplement this paper by further details as soon as satisfactory results have been obtained. Considering, however, the length of time which has elapsed since I first began to experiment in this line until to-day, when I bring the first results of those experiments before you, I have no hesitation in recommending those who are anxious to avail themselves of electricity in a portable form to make for the present the accumulators the base of their apparatus.

TRAUMATIC CATARACT; ABSOLUTE DISAPPEARANCE OF LENS AND CAPSULE WITHOUT OPERATION; PERFECT VISION WITH (?) POWER OF ACCOMMODATION.

BY T. H. BICKERTON,

LATE CLINICAL ASSISTANT, MOORFIELDS OPHTHALMIC HOSPITAL.

THE case recorded below is one of such unusual occurrence and of so unique a character that I think it is quite worthy of being put on record. It occurred in the practice of Mr. Shadford Walker, and I am indebted to that gentleman for the privilege of publishing it.

Mr. T. H——, aged fifty-six, consulted Mr. Shadford Walker in May, 1884, on account of a "cold" in the left eye. "It is," he said, "my only working eye, and I am very anxious about it." Noticing that the iris of the right eye was very tremulous, I asked what had happened to it. His answer was that it was almost useless; he had had an injury to it when a young man, and could now only distinguish large objects with it. Further inquiries elicited the following history. Twenty-nine years ago (when twenty-seven years old), whilst working in a foundry, he was struck in the right eye with a piece of steel, and within six months from the time of the accident he became quite blind, owing to the formation of cataract in that eye. He was recommended by an oculist to submit to an operation for the removal of the cataract, but declined, preferring to remain

with one good eye rather than run any risk of the operation affecting in any way the sight of the left, which was perfect. For three years and a half he remained in total blindness with the right eye. One day when passing through some very sandy ground a quantity of sand was blown into his eyes, causing him to shut them violently. On reopening them, to his surprise, he found that he could see with his right eye, being able to count his fingers, and his medical man, on whom he called immediately, told him that the cataract had disappeared. From that time until the present, twenty-five years and a half, he consulted no one about the eye, and has been content to go about able to see with it any large object. He has frequently tried to obtain from opticians a glass that would help him, but without success. Of late years he fancies there has been an improvement in his vision, though only very slight. Since, however, the attack of inflammation in the left eye, which has now lasted for some weeks, he has found the right eye very useful in helping him to get about; for although he could not distinguish features, he could see his way well enough to keep himself out of danger. For the last two years he has worn for the left eye a + 2 D. for doing his reading and writing.

Present condition.—Testing gave the following results:—Right eye, $\frac{2}{6}$: Sph. + 10 D., $\frac{2}{6}$, perfectly. Sph. + 10·25 D., $\frac{2}{6}$, perfectly. Sph. + 10·50 D., $\frac{2}{6}$, perfectly; $\frac{2}{9}$, perfectly. + 10·75 D., $\frac{2}{6}$, perfectly, but not so good. Thus, at a distance he had not only perfect vision; but an acuteness of vision beyond the normal. One point I noticed in the examination was that if the + 10 D. was put up immediately after the + 10·50 D., he could only read with it $\frac{2}{12}$, it being a moment or two before the $\frac{2}{6}$ came into view. Left eye (fixed pupil due to recent iritis), $\frac{2}{9}$: Sph. + ·75 D., $\frac{2}{6}$. Right eye: Sph. + 14 D., Jaeger 1, with ease. With the + 14 D., and bringing the type slowly towards him, he was able to distinguish words, when the print had been brought to 12½ in. from the eye, at a distance of 9 in. the print became most distinct, and it was not until it was brought to within 6½ *in. from* the eye that the print became too indistinct to read. Not only, therefore, was his near vision perfect, but it was also evident from his statements that he had a very extensive range for near vision. Left eye, sph. + 2·50 D. Jaeger 1, easily. The right pupil in ordinary light was 2½ mm. in size, dilating in the dark to 4½ mm., and contracting on exposure to bright light to 2 mm. On the eye being directed from a distant object to an object held close to the eye, either with a lens before the eye or not, the pupil contracted, the change being from 2½ or 3 mm. to 2 mm. (Great care was taken that the amount of light was the same both for the distant and near object.) The iris was very tremulous, hanging in its normal position, pupil circular, dilating and contracting regularly to variations in light. There was no sign either of lens or capsule. A careful examination and accurate focusing did not lead to the detection of any membrane whatever. The cornea showed a minute faint opacity just above and to the inner side of its centre, indicating where the piece of steel had struck the eye. On ophthalmic examination the disc was normal both as to tint (pale) and size of vessels. The fundus was normal, and though I looked carefully I could find no foreign body or irregularity existing on the surface of the retina.

Two points of interest occur in this case—the idiopathic and complete disappearance of the lens and capsule, and the apparent existence of accommodative power in an eye minus its lens. The first is a pure example of the operation of solution, and the result is that aimed at by every oculist who operates upon a soft cataract. The piece of steel acting the part of the surgeon's needle must have wounded the lens capsule, admitting the aqueous fluid to the lenticular substance. This in its turn would undergo disintegration and eventual absorption, but the process here went further and caused absorption of every particle of the capsule, thus making a perfect result. Though this latter does occasionally occur after operations both on soft and hard cataracts, it is not of common occurrence. Apparent existence of accommodative power in an eye minus its lens. It is well known that on either side of our strictly mathematical focus for near objects (p.p.), there is a small range of space in which we can see, provided the circles of diffusion are cut off by means of a stenopaic hole, but this space is never very great, and in no experiment that I have made does it extend to six inches. To what, then, can the range for near vision in the present case be ascribed? To accommodation? If so, in what manner does it act? As I have been unable to find any references to the question of accommodation in an eye minus its lens which throw any light on the point, I should be glad of any information.

In conclusion, I have to thank Mr. Shadford Walker for verifying my statements with regard to the distances at which Mr. T. H—— was able to read.

Liverpool.

TWO CASES OF

HERNIA OF THE LUNGS INTO THE NECK;

ONE VERIFIED BY POST-MORTEM EXAMINATION.

BY SURGEON-MAJOR MAURICE KNOX, A. M. D.

THE notes of the following two cases may be deemed worthy of record. They are the only instances of displacement of the lung into the neck that have come under my personal observation; although such a lesion is, I am aware, described by Dr. Roberts.

Private W——, 2nd East Surrey Regiment, aged twenty-two years, a delicate thin man, was admitted into the Station Hospital, Bareilly, under my care, on June 30th, 1884, with the following history. He had been fairly healthy up to December, 1882, when he was admitted into hospital at Gibraltar with bronchial catarrh, and remained a hundred and forty-six days under treatment. He was subsequently twice in hospital under the head of "bronchitis." He stated that in February, 1884, while on the march, he had a violent fit of coughing, and felt something give way in the left side of the neck. The pain was rather severe at the time, but he was able after a short rest to walk into camp On looking at himself in the glass, he observed a tumour above his left clavicle the size of a hen's egg. He continued to perform his duty up to June 30th, when he presented himself at hospital complaining of slight pain in his chest, dyspnœa on exertion, and dry cough. On examining the patient's chest there was marked resonance over the left side, the whole cardiac region appeared to be covered with lung tissue, the inspiratory murmur was short and the expiratory murmur prolonged. There was a peculiar crackling râle audible over the whole of the front of the left lung, especially along the thin edge. Above the left clavicle there was a tumour about the size of a turkey's egg; it was superficially situated, soft and compressible to the feel; and on auscultation respiratory sounds were audible over it, accompanied by the same crackling râle heard below the clavicle over the left lung. When the patient coughed the tumour became more prominent; the skin over the tumour was free and quite healthy; there was no impediment to the circulation or symptom of pressure of any kind; and the only inconveniences the patient experienced were slight pain in the chest and dyspnœa on exertion. The right lung was fairly healthy. The patient remained in hospital up to December, 1884, and the only change that has taken place in the case is that the lung hernia has increased to the size of a large orange. No treatment of any kind further than rest has been attempted.

Dr. Wilkie, of the Indian Medical Service, who was greatly interested in the case, has kindly supplied me with the following notes of a very similar case that, strangely enough, occurred in his own practice about the same time:—

Jewra, aged fifty, a native prisoner in Bareilly Central Prison, a man who frequently suffered from attacks of asthma, was admitted into hospital on July 2nd, 1884, suffering from fever and general debility. He died suddenly from syncope, about half an hour after returning from the latrine, on July 8th, 1884.

Post-mortem examination. — The body was thin and very slightly jaundiced. The heart was pale and flabby, the left ventricle being hypertrophied. The left lung was emphysematous, especially along the anterior border and at the apex. The right lung was emphysematous on the anterior border; the apex was protruded beneath the clavicle into the neck. It was dilated into a translucent tumour about the size of a man's fist, in which most of the alveolar structure of the lung had disappeared. On removing the lung the entire hand could be passed upwards beneath the clavicle from the cavity of the thorax, and the superficial structure of the neck bulged out into a tumour. In the left lung the emphysema was in a less advanced stage, and there was no protrusion upwards. The lungs showed otherwise nothing abnormal except a little muco-pus in some of the tubes, and perhaps a little thickening of the tubule walls. The kidneys

were mostly clear but somewhat mottled, with the Malpighian bodies standing out very red and distinct. The spleen was small and soft. The liver was hyperæmic and very slightly jaundiced; the acini were somewhat marbled and nutmeggy in character, with large red centres and pale circumferences. The stomach and intestines were healthy.

Barcilly.

SUCCESSFUL OPERATION ON A REMARKABLE CICATRICIAL BAND.

BY GEORGE WHERRY, M.C., F.R.C.S. ENG.

AN undergraduate aged twenty-four, looking very pale, worn, and ill, consulted me in November, 1882. I discovered a large cicatricial bridge, which joined together the buttocks, overlapping the anal orifice, and a long sinus-like tunnel extending beneath it with two openings—the one near the anus, and the other over the sacrum; these discharged a quantity of feculent pus, and the poor fellow had to wear napkins, and change them frequently. The band, which in the narrowest part measured seven inches in circumference, was the result of a scald in infancy, for a hard-handed nurse had dipped his buttocks in boiling water. The patient was put under ether, and the band cut in the middle line. The hæmorrhage was not great, and a complete recovery followed the operation. The tendency of the granulating surfaces to unite was prevented by introducing carbolised oiled lint to the bottom of the wound. The patient was driven to seek advice about some bladder irritation which was clearly reflex, and it was only in the course of a systematic investigation to find a cause for this that his real malady was discovered. There had been no troubles directly or indirectly connected with the cicatrix until the few months previously, and he had been advised by an eminent surgeon not to have it interfered with. The inflamed and suppurating condition described was brought on by boating, for, to my great surprise, I learned that he had been sculling nearly every day in spite of discomfort, failing strength, and loss of weight.

This appears to be a good example of the growth of a cicatrix; probably about the size at first of an infant's hand, it gradually enlarged with the body's growth until it attained the size of an adult's hand at manhood.

RADCLIFFE INFIRMARY, OXFORD.

A CASE OF ULCERATIVE ENDOCARDITIS IN A CHILD, AFFECTING THE PULMONARY VALVES, WITH CERTAIN CONGENITAL DEFECTS IN THE HEART; NECROPSY; REMARKS.

(Under the care of Dr. TUCKWELL.)

THE following case of ulcerative endocarditis will be read with considerable interest in connexion with the Gulstonian Lectures on Malignant Endocarditis recently delivered by Dr. Osler, and published in THE LANCET of March 7th, 14th, and 21st. It was apparently a primary disease of the pulmonary valves, and there appears to have been no disease on the left side of the heart; of the large number of cases collected by Dr. Osler, the disease appears to have been limited to these valves in only five. The age of the patient and the physical signs found on examination of the chest, in the absence of further symptoms of embolism, made the case one which it was almost impossible to diagnose correctly. For the following notes we are indebted to Dr. Harris, house-physician to the infirmary.

H. E——, a boy aged four years, was admitted to the Radcliffe Infirmary on Nov. 25th, 1884, and died on the 30th of that month. He was said to be suffering from "congestion of the lungs," and during the five days that he lived after admission he was so ill that no very detailed examination could be made. The father stated that the boy had always appeared to be the healthiest of his family of four; that he had had very little previous illness, but that in the previous month of May he had measles, from which he recovered, though not regaining quite his former robust state of health. He seemed fairly well till about three weeks before admission, since when he had kept his bed, suffering from loss of appetite, cough, and a hot flushed face. On the night of admission the child was very flushed; temperature 101°; pulse 180, and regular; respiration 54. What physical examination of the lungs could be made revealed nothing definite, but he was believed to be suffering from acute pneumonia.

On the following day (Nov. 26th) there was evidently a great change. The child, from being very flushed, was now very pale, with slight blueness of the lips and a small blue patch on each cheek. The temperature in the morning was 103°; in the evening 103·6°. Respiration in the morning 54; in the evening 66. Pulse in the morning was 130; in the evening over 180, but the exact rate could not be obtained. The child's general condition was very low, and very little examination was made, but there was thought to be a faint pleural friction sound at the base of one lung, and also at the cardiac apex a distinct though faint murmur, which was apparently systolic in rhythm, but from the rapidity of the heart's action it could not clearly be localised. On the next morning (the 27th) the temperature had fallen to 99°, but there was no corresponding improvement in the general condition of the child; the face still presented the peculiar pallor, with the slight blueness of lips and cheeks. In the evening of the same day the temperature was 103·2°, respiration 54, and pulse over 180. On the following morning (the 28th) the general condition was the same. Temperature 104°; pulse 162; respiration 54. In the evening the temperature was 102°; pulse 156; respiration 54.

The next morning (the 29th) showed a fall of temperature to 101·4°; respiration 58; pulse 158. The child since admission had been always conscious, never delirious, but had taken very little notice of anything going on in the ward. On this day the systolic murmur was still audible, and there was evidence of some lesion at various parts of the lungs, but the child was far too ill to be moved much for an examination to be made. Behind, at the right apex, was marked tubular breathing; at the right base, dulness of slight extent, with no definitely abnormal auscultatory signs; over the left apex in front was some impaired resonance, but again no definitely abnormal signs on auscultation. The child had some cough, though it was not troublesome. It was only on this day that a history of the case could be obtained. In the evening the temperature rose to 102·6°; pulse 156; respiration 48.

On the morning of the 30th, the day on which he died, the temperature was 102·4°; respiration 54; pulse 158, regular. His general appearance was unchanged; there were still the pallor and blueness of the lips and cheeks, but in addition there were noted a distinct internal squint of the left eye and ptosis of the upper eyelid of the same side. Abdomen somewhat distended; no tache cérébrale. There was now marked dulness over the left infra-clavicular, left mammary, and axillary regions, with bronchial breathing over the infra-clavicular and marked tubular respiration at the axillary and lower scapular regions, also a doubtful friction sound over the lower part of the left infra-clavicular region. There had been diarrhœa since admission, the number of motions varying from two to five in the twenty-four hours, and these were of a green slimy character. His breathing became more and more oppressed, and he died about 7.30 P.M. The temperature just before death was 101·6°.

The post-mortem examination, which was made seventeen hours after death, revealed extensive ulcerative endocarditis affecting the orifice of the pulmonary artery, a patent foramen ovale, a communication between the right and left ventricles, and numerous pulmonary infarcts. The body was fairly well nourished, and for the age well developed. Post-mortem decomposition was not marked. Cutaneous hypostases dorsal. Pericardium and heart: The pericardium contained about six drachms of turbid effusion, which was not blood-stained. The visceral surface of the sac showed numerous small patches of quite recent lymph, and also here and there a few hæmorrhages the size of pin heads.

The pericarditis was evidently of quite recent date, and there were no adhesions between the visceral and parietal layers. The heart was considerably enlarged, weighing four ounces; the apex was formed entirely by the right ventricle. Muscular substance firm. Walls of both ventricles much thickened; the thickness of the right exceeding that of the left. The section of the right ventricular wall near the tricuspid orifice was from a quarter to three-eighths of an inch, while that of the left ventricle at a corresponding point was a quarter of an inch. (These measurements were not taken at the time of the post-mortem, but after some days' immersion in alcohol.) All the cavities contained some dark blood, partly fluid, partly in dark coagula, the right side considerably more than the left. On removing the heart, the pulmonary artery was seen to be completely blocked by a very firm thrombus, which was markedly adherent to the walls of the vessel, and was of yellowish-grey colour throughout. On section no portion of this thrombus appeared dark, and no portion of it was softened; it could not be readily separated from the arterial wall; when torn away it left visible an extensive ragged irregular ulcer, which extended from the origin of the pulmonary artery upwards a distance of an inch and a quarter into the vessel, and was not limited to one side of the artery, but extended all round the vessel. No trace of the semilunar valves could be seen, but they appeared to have been completely destroyed in the ulcerating process. Although the ulcer was so large, it had not extended deeply into the walls of the vessel, nor had it at any point nearly perforated the arterial wall. The tricuspid orifice admitted the tips of two fingers, and the cusps of this valve were perfectly healthy, though the ulcer in the pulmonary artery extended as far as the base of attachment of one cusp. The endocardium of the right auricle and ventricle was healthy. The foramen ovale was patent, and would admit the passing of a No. 12 English catheter; but the communication between the two auricles was not direct, for a fold of endocardium from the margin of the fossa ovalis lay loosely over the aperture, and, acting probably as a valve, prevented the passage of blood from the right to the left cavity. At the upper part of the septum ventriculorum was a circular opening, fully one-eighth of an inch in diameter, forming a communication between the two ventricles. This opening was situated immediately below the ulcerated surface in the pulmonary artery, scarcely one-tenth of an inch of healthy endocardium intervening between them; yet the ulcerating process had had nothing to do with the formation of this opening, for the latter had perfectly smooth rounded margins, covered by an apparently healthy endocardium, and was evidently of congenital origin, forming a direct communication between the two ventricles. The mitral orifice admitted the points of two fingers, but less readily than the tricuspid; its valve was perfectly healthy. The aortic valves and the aorta itself were normal. Pleuræ and lungs: Both pleuræ contained a small amount of clear serous fluid, and showed, especially on their diaphragmatic surface, several minute punctiform hæmorrhages. The upper and lower lobes of the left lung were united together by recent lymph. Lungs: Both lungs contained numerous recent infarcts. The largest of these was in the upper lobe of the left lung, which was quite solid, except at the very apex, and dark-red in colour. One or two smaller infarcts existed in the lower lobe of the left lung; one of these being on section grey, though firm, and appearing to be the oldest present, for all the others were of dark-red colour, and none were softened. In the right lung the infarcts were more numerous but smaller, and chiefly, though not entirely, situated in the lowermost lobe; none were softened even in their centre. The spleen weighed three ounces, was firm, and presented no recent infarcts, but at one part on the surface was a large, white, starred cicatrix, such as is often seen as the result of an old infarct. The liver and kidneys were healthy; in the latter the fœtal lobes were very distinct. Peritoneum: No hæmorrhages could be found. Stomach and intestines: The mucous membrane of the stomach appeared pale, but otherwise healthy. The small intestines contained a large amount of partially digested milk; their mucous membrane was pale. Peyer's patches and the solitary glands were remarkably distinct throughout their whole length; but they were pale and not surrounded by any hyperæmic zone, and, though they were so distinct, were only just raised above the general mucous surface. There was no ulceration at any part of the intestines. The large intestines were normal. The mesenteric glands were somewhat enlarged, pink in colour, and firm in consistence. The brain and its membranes were carefully examined, but nothing abnormal was found. Special examination was made for any lesion which would account for the symptoms referable to the left eye observed during life.

Remarks by Dr. HARRIS.—Cases of ulcerative endocarditis are sufficiently rare, and present frequently so many difficulties in diagnosis that it has been considered worth while to record the above case. From the clinical features presented in the majority of cases it has been found convenient to group them under two heads and to speak of a pyæmic and of a typhoid variety of the disease. The above case could not be placed in either of these groups; it never for a moment suggested a resemblance either to pyæmia or to enteric fever; it presented special characters of its own, and these characters were due to the unusual position of the lesion. On admission, the child was believed to be probably suffering from acute pneumonia, and it was not until the following day, when its appearance became so much altered and the history of the case was obtained, that it became evident that, although pneumonia might be present, it was not sufficient to explain all the symptoms and that there must be some other lesion as well. The cardiac murmur, though distinct and believed to be systolic in rhythm, was never a loud one, and the frequency of the heart-beats was so great that we could not be certain as to the rhythm of the murmur or as to the importance to be attached to its presence. The squint and the ptosis observed during the last day of the child's life inclined us to the diagnosis of acute tuberculosis; but there were still wanting other confirmatory symptoms of tubercular meningitis. Pathologically, the case was interesting from many points of view. Ulcerative endocarditis affects far more commonly the left than the right side of the heart, and the age of our patient was far younger than that at which the disease is usually seen. Why should the lesion in this instance have affected the pulmonary artery, which is so rarely the seat of any acute disease? It has been observed that very many of the cases of ulcerative endocarditis occur in hearts which have previously been the seat of some chronic valvular mischief, the acute disease being as it were superimposed upon the already diseased endocardium. In our own case no trace of the pulmonary valves could be seen, and so they must either have never existed, or, as is quite possible, have been destroyed in the ulcerating process. Congenital defect of the pulmonary artery is among the more common forms of the congenital lesions affecting the circulatory system, and is very frequently associated with some other congenital cardiac defect, such as open foramen ovale, or a communication between the two ventricles, both of which lesions existed in the above case. Another point which seemed to speak strongly in favour of there being some lesion of the pulmonary artery of long standing was the large amount of hypertrophy of the right ventricle which was present, without any other cause to account for this, for it could hardly be assumed that so much hypertrophy had been called forth in consequence of the acute endocarditis, nor from the effect which the small aperture in the septum between the ventricles might have, and there was no lesion of the tricuspid valve. Hence we believe that primarily there was some congenital lesion of the pulmonary artery causing compensatory hypertrophy of the right ventricle, and that ulcerative endocarditis subsequently attacked this defective part of the circulatory system. The size of the ulceration was exceedingly large, especially when we consider the importance of the part it affected. As regards the infarcts in the lungs, one point seems specially worthy of notice that is, that none were softened, which so commonly ensues in the infarcts which are caused by emboli from this destructive form of endocarditis. This absence of softening can hardly be accounted for by the infarcts being of recent date; for certainly the disease must have existed for some length of time, and have been in a position, so far as extent of lesion was concerned, to give rise to emboli, which, if they had possessed their usual irritative properties, would certainly have been followed by the usual softening. That the lungs were the only organs where infarcts existed is of course explained by the position of the original lesion. Although no brain lesion was found, it seems highly probable that the ptosis and squint were the result of a small embolus. The lobed condition of the kidneys is interesting when we consider that there also existed certain congenital heart defects.

LEEDS GENERAL INFIRMARY.

TWO CASES OF FRACTURE OF THE ASTRAGALUS, AND A CASE OF SEPARATION OF THE UPPER EPIPHYSIS OF THE RADIUS; REMARKS.[1]

(Under the care of Mr. A. W. MAYO ROBSON.)

CASE 1. G. C——, fitter, aged forty-eight, fell from a ladder, a height of eight or nine feet, alighting on his feet. On admission he was found to have a fracture of the left fibula, about the junction of the lower and middle third, with some injury to the foot. On flexing the joint crepitus could be felt indistinctly. On further examination a prominence of bone could be felt in front of the ankle-joint, between the malleoli. The width of the malleoli, measured by calipers, was increased by a quarter of an inch as compared with the sound side. A line drawn from the posterior part of the internal malleolus to the tip of the heel was a third of an inch less on the injured foot. The distance from the tip of the external malleolus to the floor was decreased by half an inch, and the circumference over the malleoli was increased by an inch and a half. He was in the hospital with the leg on a back splint from Aug. 13th to Sept. 6th, when he was discharged with a plaster-of-Paris splint on. When he appeared as an out-patient on Oct. 24th the movement of the affected ankle-joint was good, limited extension being the chief fault. There were still increased circumference of the ankle, and diminution of the distance between the malleoli and the sole.

CASE 2.—G. H——, quarryman, aged thirty, fell from a plank distant some twelve feet from the ground, injuring the left foot. On admission, Oct. 9th, 1884, there were swelling of the foot and ankle, greatly impaired movement, and some deformity. On flexing the foot to a right angle and pressing upwards crepitus could be felt. The whole foot appeared to be a little displaced forwards, so that the heel of the injured side was slightly in advance of that of the sound side. The distance from the tip of the external malleolus to the floor was lessened half an inch, and a line drawn from the tip of the inner malleolus to the prominence of the heel was lessened by a quarter of an inch on the injured side. The circumference of the ankle was increased, and calipers showed the malleoli to be separated about one-third of an inch. He was treated on a back splint, the foot being brought into as good a position as possible. After three weeks plaster-of-Paris was applied, and he was made an out-patient. Two months afterwards there was fair movement in the ankle, but the increased circumference and diminished distance between the malleoli and the sole remained.

CASE 3.—A boy aged six was brought to the infirmary, the parents stating that they had noticed impaired movement in the arm during the last four months, but on closer inquiry it was elicited that he had been run over by a cart four years before, and had been at the time treated for a bruise of the arm. On admission he complained of no pain, could flex, extend, and pronate the forearm completely, but could not supinate more than to place the hand in a line vertical to the floor. The ulna could be traced along its whole length, and the olecranon bore a proper relation to the condyles, which were normal. The head of the radius was in position, but immediately below it was a hollow. The radius could be traced obliquely across the front of the forearm from below upwards and inwards, ending in a hard bossy mass, apparently callus, in front of and below the internal condyle of the humerus, where it rotated in its new position. It was diagnosed from dislocation of the head of the radius forwards by the detached head being felt in its normal position, and by the ability to completely flex the forearm. As the arm was very useful, and had apparently accommodated itself to the new condition, no treatment was recommended.

Remarks by Mr. ROBSON.—The points of interest are:—(1) The occurrence, in the practice of one surgeon, of two cases within a short time of what is usually stated to be a rare accident; but, as Mr. Bryant remarks: "Fracture of the astragalus is probably more common than is usually thought, the injury, which is difficult to diagnose, being often overlooked." (2) The termination: a useful limb resulting in both cases. (3) The signs aiding in the diagnosis being—(*a*) Presence of crepitus on forcible flexion of foot; (*b*) absence of fracture of other bones of tarsus; (*c*) lessening of distance between the tips of the malleoli and the sole of the foot; (*d*) increased circumference of ankle; and (*e*) very slight separation of malleoli. The radial case is interesting on account of its extreme rarity, and as an illustration of what can be accomplished by unaided nature.

[1] Read before a meeting of the Yorkshire Branch of the British Medical Association, Feb. 28th, 1885.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Aneurysm of Splenic Artery rupturing into Stomach.—Congenital Deformity. Osteitis Deformans.—Synovial Cysts in connexion with Joint Disease.—Primary Sarcoma of Penis. Dislocated Hip.—Fatal Hæmoptysis from Hydatid of Lung.

AN ordinary meeting of this Society was held on Tuesday last, Dr. J. S. Bristowe, F.R.S., President, in the chair. The number of specimens shown was very large.

The report of the special subcommittee appointed to inquire into the true nature of Mr. Lane's specimens of fracture of the hyoid bone and larynx was signed by Mr. Lane, Mr. Shattock, Dr. F. Semon, and Mr. Butlin. The report showed that the subcommittee agreed almost entirely with the conclusions drawn from the specimens by Mr. Lane. The reporters stated that it was clear that fractures of the hyoid bone and thyroid cartilage were much more frequent than had usually been supposed. The most interesting specimen shown by Mr. Lane they considered to be that of fracture of the cricoid cartilage, for this form of fracture had been regarded as almost invariably fatal; Mr. Lane's specimen showed that such a severe injury may be recovered from; there was considerable displacement of the fragments and no doubt considerable violence must have been used. The absence of the clinical history of these cases was to be regretted, but under the circumstances this defect could not be helped.

Dr. S. WEST exhibited a specimen of Aneurysm of the Splenic Artery Rupturing through the Stomach. It was taken from a male subject aged fifty-six, who had suffered from hæmatemesis and was given to drink. He had had a similar attack of hæmatemesis fourteen years previously. He suffered from great pain and flatulence with looseness of the bowels. When he was admitted on January 18th, 1885, he was weak and faint and passed much blood in the motions, which were long afterwards of a tarry aspect. The patient was anæmic; there was slight enlargement of the liver and some tenderness of abdomen. On January 28th a pint of bright blood was vomited and in half an hour the patient died. The stomach was found at the autopsy to be full of blood; there was an ulcer one inch in length, and situated midway between the œsophagus and pylorus. An aneurysm of one of the chief branches of the splenic artery was found to be adherent to the stomach on the one hand, and on the other to the pancreas; there was much chronic inflammatory tissue around the aneurysm. A prominence projected through the base of the ulcer in the stomach. There were two slight losses of substance at other parts of the stomach, which were of old date. The liver and kidneys were cirrhotic; the pleuræ were adherent. The disease was rare, and there had been but two cases recorded in the Society's Transactions. One was recorded by Dr. Pearson Irvine, in which the aneurysm was situate on the hepatic artery. The other case was reported by Dr. Powell, and in it the coronary artery was the seat of the aneurysm; both these authors likened the occurrence of their specimens to the aneurysms found in chronic cavities of the lungs. Last year Dr. Carrington had recorded a somewhat similar case. The great pain which preceded the hæmorrhage was a noteworthy clinical feature.—Dr. BARLOW said that he had recently seen a specimen at University College Hospital which corresponded almost exactly with the one Dr. West had described. He was not aware that these cases were very rare, or he should have shown his specimen. There was a large ulcer measuring three inches in diameter, and the pancreas formed part of the base of the ulcer, into which a pea-sized aneurysm projected.—Dr. NORMAN MOORE thought aneurysmal dilatations of the pancreatico-duodenal artery

were not uncommon, and that they were the rule in cases of hæmatemesis due to gastric ulcer.

Mr. TREVES read a paper on a case of Congenital Deformity, which he had exhibited at a previous meeting of the Society. The case was that of a man aged twenty-four, who was publicly exhibited as the "elephant" man. The skin and the bones were chiefly affected. The disease of the skin was of a twofold character, and consisted of an increase in the subcutaneous cellular tissue, which hung in heavy folds from different parts of the body, and in the more dependent places became quite pendulous; these folds were to be seen in the right pectoral region and on the buttocks, where they were so dependent that they reached the middle of the thigh and interfered with the act of defecation. The whole of the back and the entire extent of one upper limb was involved in the disease. The second character of the cutaneous affection was the presence of congenital papillomatous tumours situate on the hypertrophied cellular tissue. With the exception that the papillomata were larger than usual there was nothing special about them; some of the tumours were as large as the top of the forefinger, and the head was the only part of the diseased area which did not possess these papillomata. The head was greatly enlarged, and its circumference was almost equal to that of the waist. Large exostoses on the skull gave it an outline so irregular that its shape was almost indescribable. The right superior maxillary bone was affected in the same way, and from the front of this bone there projected a large fibrous mass, which the patient spoke of as his trunk; the nose was completely turned round to the left. The bones of the right upper limb were greatly hypertrophied, and the limb was three or four times as large as the left. The bones of the feet were enlarged in the same way. The patient averred that the affection was congenital, and that the size of the affected parts held the same relation to the rest of his body in his childhood as they did now.—Dr. RADCLIFFE CROCKER said that the case belonged to that class which had been described as dermatolysis and pachydermatocele. A specimen somewhat similar had been reported by the late Dr. Tilbury Fox; in this instance the buttocks were the seat of a large hypertrophy, and hung down in three or four flounces as low as the hams. The additional interest of the exostoses in Mr. Treves's case was referred to. He (Dr. Crocker) looked on the tumours as of the nature of molluscum fibrosum. It was probable that the nervous system governed the distribution of this disease. Dr. Tilbury Fox's case appeared to have originated from an injury which caused an abscess, after the opening of which the disease developed.

Dr. SILCOCK exhibited specimens from a case of Osteitis Deformans, which were taken from a woman aged eighty-two, who was admitted into St. Mary's Hospital for strangulated hernia, which was reduced by Mr. Pepper. There was no obvious enlargement of the facial bones, but the forehead was very prominent. The femora were curved slightly, with the convexity outwards and forwards. The tibiæ were curved forwards in their upper two-thirds, and both these bones appeared to be much thickened. The right tibia was much thickened in its upper half, due to an increase of the compact tissue. The medullary tissue was encroached upon by the compact tissues to a greater extent anteriorly than posteriorly. At the summit of the curve anteriorly, the compact tissue was more porous than elsewhere; no new growth was detected anywhere. The periosteum was perhaps a little more adherent than natural. The cranial sutures were obliterated from ossification; the pericranium was not abnormally adherent. The bone was smooth and mottled by areas of congestion, and grooved by vessels here and there. The right frontal and parietal eminences were greatly thickened. The frontal bone in the mid-line was one inch and a quarter in thickness just above the superciliary ridges. The squama of the temporal bones were one-third of an inch in thickness on the right side, and a quarter on the left. The mid-line was half an inch in thickness one inch above the parieto-occipital suture. The distinction between the internal and external tables and the diploë was lost, but the centre of the frontal bone was pale and porous, and could be indented by the thumb-nail. Some areas of reddish, soft, medullary tissue were found irregularly distributed in bone which was more porous than the rest. The grooves of the vessels were irregularly deepened. The bones of the base of the skull were not involved in any marked degree. The dura mater was much coarser in structure than natural. The spine was curved abnormally, but the bones were not obviously diseased. The other organs showed no abnormal changes worthy of note. The specimens closely corresponded with those described by Sir James Paget in the fifty-seventh volume of the Medical and Chirurgical Transactions; and Dr. Silcock agreed with Mr. Butlin's interpretation of the pathological appearances, but referred more specially to the great vascularity of the parts, and to the imperfect structure of the new bone which had been thrown out. The chronic inflammatory nature of the osseous disease had also been supported in a paper contributed to the St. Thomas's Hospital Reports by Mr. Lunn, who maintained that osteitis deformans was a constitutional disease, producing atrophy and absorption of a large part of the osseous system, with consequent weakening of the bones, so that they yield when exposed to strain. The compensatory formation of bone might be looked upon as an ill-developed callus. In this case no tumour was found. The right tibia was the most markedly affected. He also showed the bones removed from a child aged thirteen, in which both tibiæ were affected much in the same way as in a case of osteitis deformans. In the child the disease was the result of congenital syphilis. As proving the antiquity of the disease, he showed specimens taken from a sepulchre.—Dr. GOODHART showed recent specimens from a case of osteitis deformans. The patient had died of bronchitis. There was no evidence of tumour in this case, if we except a fibroid tumour of the uterus. The head was the first and chiefly affected; the lower jaw was also the seat of enlargement. The other bones were really affected, though this was not determinable during life. After removal the bones were very heavy, though their shape was unaltered. The spinal column was not affected with marked changes, but a gradual yielding of the spine had led to diminution of the stature of the patient.—Mr. STEPHEN PAGET gave some further details of the cases recorded by Sir James Paget in the sixty-fifth volume of the Medical and Chirurgical Transactions. He had examined the tibia of the case of an old gentleman; the clavicle was also affected; the changes were of a typical kind. Of two cases he had recently seen one had a soft molluscous tumour, and the other a pigmented tumour in the right groin. In one specimen which he had examined the amount of rarefaction that had taken place was remarkable, and the porous bone was filled with soft gelatinous granulation tissue, and this alteration made the bone so crumbling and coarse that it was impossible to trephine a portion. This kind of change proved that no theory of compensatory hypertrophy or outgrowth could possibly account for the state of the skull, which was unquestionably the result of a chronic inflammatory process.—Mr. H. T. BUTLIN said that he had examined some skulls in the South Kensington Natural History Museum, and the Neander-thal skull to be seen there appeared to him to be a specimen of a diseased condition, and he believed that it was an example of that *modern* disease which had developed within the last few decades! The great development of the superciliary ridges was a notable feature, and in Dr. Silcock's case these ridges were greatly hypertrophied. The deep depressions for the Pacchionian bodies and vessels also bore out his contention. The thigh bones were curved and thickened. Everything considered, he thought that osteitis deformans was the same disease as that which gave rise to the peculiar Neander-thal skull. Mr. B. SUTTON said that Schaffhausen had concluded that the Neander-thal skull was a rachitic one, though Professor Huxley opposed that view. He was of opinion that Mr. Butlin was correct in his views on the subject.—Mr. EVE said that he had examined the tibia of one of Sir James Paget's cases. The medulla was almost diffluent, and was of a bright-red colour; there was a great abundance of young cell elements and a great amount of brown pigment; these were evidence of a sub-inflammatory process. He had observed also fibrous degeneration of the cartilage, which he believed was the expression of a diathetic condition, and of frequent occurrence in osteitis deformans.—Mr. BOWLBY said that in some specimens he had examined there was a growth of new bone, as was to be well seen in the femur of a man who had suffered from osteitis deformans; the head of the bone showed changes like those of rheumatoid arthritis. He had observed the hypertrophy of the superciliary ridges of a woman aged sixty-two, in whom the body had become shorter.—Dr. CARRINGTON could hardly admit that there were any signs of rarefaction of the bone in the specimen shown by Dr.

Goodhart. The condition which Sir James Paget described could not be harmonised with that of the bones which he had recently moved from the body of a woman at Guy's Hospital.—Mr. EVE explained that there was rarefaction of the bone in the neighbourhood of the medulla in the specimen he had examined.

Mr. D'ARCY POWER read a paper on Synovial Cysts in connexion with Joint Disease. The first specimen described was that of the left knee of a man aged forty-four, who came under observation in March, 1884; a swelling existed in the calf and some glairy fluid tinged with blood was withdrawn by a syringe. There was a direct communication between the cavity of the joint and the synovial cyst. A hernia of the synovial membrane also projected from the back of the capsule of the joint. The left knee of a girl aged twenty-two was also shown; in this case there had existed a swelling in the calf of six weeks' duration; the joint was disorganised; on its posterior aspect two openings were visible and the cyst was in communication with the joint. The bursa under the semi-membranosus was the probable origin of this cyst. A cast from a case of rheumatoid arthritis was shown in which a rounded swelling was present in the calf, and was found to be an enlarged synovial cyst. Another cast was shown. The question as to whether the cysts were the result or the cause of the joint disease was discussed. M. Fouchet and Mr. Baker had written on this subject. Injection of iodine into the cyst sometimes led to a transient synovitis, and at other times more serious mischief resulted. The origin of these synovial cysts was discussed. The escape of synovial fluid into the tissues under the tendon of the popliteus was a possible mode of origin, and normally a bursa had been described there by Mr. Holden. In cases of joint disease it was reasonable to suppose that an increase in the quantity of the synovial fluid might lead to a pouching which would be directed by the popliteus muscle towards the calf; but this was not always the mode of origin of these cysts, for they sometimes originated by an enlargement of the bursa under the semi-membranosus, which bursa occasionally communicates with the joint. In only one case was the cyst found in connexion with osteo-arthritis.

Mr. STEPHEN PAGET showed a living specimen of large synovial cyst in association with disease of the hip-joint. The case was that of a man, who began in 1874 to suffer pain with a stiff knee. The left hip was stiff, as was also the knee. A fulness and sensation of fluctuation were found in the upper part of the thigh below Poupart's ligament. Extension by a weight of 10 lb. was the treatment first adopted. Later on the stiffness of the hip and knee increased, and the thigh became everted, and the limb shortened three-quarters of an inch. A large hemispherical swelling measuring seven and a half inches from above downwards by seven inches across existed below Poupart's ligament, from which forty-two ounces of oily yellow alkaline fluid, having a specific gravity of 1028, and full of fat and cholesterine, were withdrawn. Again, in 1884, forty ounces of fluid resulted from a fresh tapping. The pains and stiffness had increased. The pupils and knee-jerks were normal. He suggested that the bursa under the psoas might have been the seat of cystic dilatation, but the fluid was not of bursal origin. The man had been in the habit of drinking large quantities of synovial fluid obtained from the butcher's.—Mr. M. BAKER referred to his paper published in the St. Bartholomew's Hospital Reports. He had since seen three cases in connexion with the elbow, and one with the shoulder-joint, besides several about the hip-joint. The clinical and pathological importance of these cases was great. Such collections of synovial fluid might, when tapped, lead to inflammation and suppuration in the associated joints, and thus indirectly to amputation.—Mr. EVE spoke of a case in which a cyst under the gastrocnemius was unconnected with the knee-joint. He alluded to the specimen of a knee-joint of a horse in which a cul-de-sac projected into the sheath of the tendon. Verneuil had described similar conditions.—Mr. M. SHEILD said that the tapping of such synovial cysts was not devoid of risk. He briefly referred to a case in which many large cysts were in connexion with a diseased joint, and after the introduction of a grooved needle the joint became the seat of destructive inflammation and death ensued. About the wrist-joint such cysts also occurred. "Ganglionic disease of joints" was the phrase applied to such cases. He narrated briefly the case of an aged man in whom this affection existed; diffuse suppuration in the forearm resulted from tapping the cysts. In view of the serious consequences which followed puncture, he thought amputation ought to precede puncture of the cysts.

Mr. BATTLE showed a specimen of Primary Sarcoma of the Penis. The patient was first seen in 1883; he was sixty years of age. The penis had undergone a gradual enlargement without giving rise to pain; some slight attacks of hæmorrhage were the only noteworthy signs. The end of the organ was enlarged, and presented a dark-coloured and spongy appearance. There was no enlargement of the inguinal glands, no albuminuria, and no enlargement of the liver. On Nov. 26th Mr. Battle amputated the penis close to the pubes; some transient retention of urine followed, but no inflammatory swelling disturbed the course of the case. The patient left the hospital, but died forty-three days after the operation. The final symptoms were thirst, jaundice, and hiccough, with the signs of exhaustion. On section the tumour presented a smooth and elastic appearance, whilst its free surface was shaggy and fungating; there was no trace of the glans; the structure of the corpora cavernosa seemed natural. Microscopically, cells of various kinds, of which the majority were round cells, were seen. The round cells had well-marked nuclei, and in places there was a tendency to alveolar grouping; some of the cells appeared to be of inflammatory origin. The case was an example of a rare disease, and he knew of but two other cases; one recorded by Mr. T. Holmes, of a melanotic sarcoma of the penis, and the other mentioned in Gross's "System of Surgery," in which death followed removal of the penis. Mr. Golding Bird had mentioned to him a case of melanotic growth of the penis.—Mr. GOLDING BIRD said that his case occurred four years ago. There were two lumps on the penis, one was dark coloured, and resembled a chancre. The growth was of the spindle-celled variety; there were no secondary deposits; the penis was amputated, and the patient did well.—Dr. SEYMOUR SHARKEY had seen one specimen of mixed-celled sarcoma of the penis, which had been mistaken by the surgeons for epithelioma.

Mr. STEPHEN PAGET showed a specimen of Dislocated Hip. It was prepared from a cabman aged sixty-eight, who received a severe injury from a cart-wheel. The limb was flexed, adducted, and rotated in; the head of the bone was not clearly made out during life. The man was intemperate, and died from severe bronchitis. The bone was replaced by manipulative movements. Acute diarrhœa set in three days after the operation. Death ensued eight days after the injury, from exhaustion. The internal viscera were decidedly diseased; there was much pigmentation of the intestines, which could be traced in between the muscular fibres. At the autopsy much bruising of the fascia lata was seen, and the head of the bone was below the obturator internus and gemelli, which had been slightly torn; the quadratus femoris was torn across; the sciatic nerve looked as if it had been stretched; the obturator externus was uninjured; the rent in the back of the capsule was very large. Mr. Paget thought the dislocation was the result of direct violence.—Mr. CHARTERS SYMONDS said it was possible for the backward dislocation to have occurred when the man fell rather than as the effect of direct violence.—Mr. BOWLBY said that the cotyloid ligament was torn off immediately behind, and it was obvious that the dislocation had resulted from direct force; attempts to dislocate by abduction showed that the head of the bone could not be brought into correspondence with the rent in the capsule by this means.—Mr. EVE said that the rent was below the obturator internus, and he thought that the dislocation had first taken place directly backwards, and afterwards the bone had slipped upwards.—Mr. PAGET, in reply, urged that in attempts at abduction the head of the bone went right away from the rent in the capsule, and so the dislocation could hardly have been caused after the usual method.

Dr. PERCY KIDD ready a paper on a case of Fatal Hæmoptysis from Hydatid of the Lung. The patient was a female aged forty-two, admitted into Brompton Hospital on August 25th, 1884, under the care of Dr. Tatham. There was a history of jaundice fifteen years before. A year ago the patient had suffered from "inflammation of the left side of the chest." For the last two months she had complained of pains in the chest, cough, slight expectoration, occasional hæmoptysis and wasting. There was a blue line on the gums. There were signs of consolidation at the apex of the left lung, without râles. The temperature rose for a day or two. The chief symptom was persistent hæmoptysis. The total amount of blood brought up was large, though there was never

very free hæmorrhage. Three months after admission there was absolute dulness, with almost complete absence of breath sounds over the upper part of the left lung, and some crackling râles were heard over the same area. There was no bulging of the chest. On Dec. 20th she suddenly coughed up a large piece of membrane, and a few minutes later brought up two large saucer-shaped clots. Shortly afterwards there was considerable hæmoptysis, and the patient died. No clear fluid or daughter cysts were coughed up at any time. At the autopsy the upper lobe of the left lung and the upper margin of the lower lobe were in a state of pinkish-grey fibroid induration. There was a single cavity on the upper lobe as large as a duck's egg, with thin tough walls, which were somewhat shreddy and infiltrated with blood. The cavity contained no blood or fluid of any kind, and no hydatid membrane. Two large bronchi led directly into the cavity, and showed some superficial ulceration at their entrance into the cavity. The lower part of the lung was healthy. There was a small fibroid patch at the right apex, and some spots of inhaled blood at the base of the lung. The liver weighed 3 lb. 10 oz.; it was smooth on the surface and of soft consistence; irregular fibroid tracts pervaded it, corresponding to the distribution of the large bile-ducts, which were dilated. There was an old hydatid cyst on the under surface of the right lobe, pressing slightly upon the hepatic duct, which was greatly thickened but only slightly obstructed. The gall-bladder was healthy. The stomach was filled with blood, but healthy. The membrane that was expectorated was typically laminated, and its inner surface was lined with large highly granular cells. No daughter cysts or hooklets could be discovered. The fatal hæmoptysis evidently resulted from separation of the cyst from the surrounding lung tissue. It seems probable that bleeding from the cavity wall determined partial detachment of the cyst in the first instance, and it was owing to the accumulation of blood between the hydatid membrane and the cavity wall that complete separation and expectoration of the cyst were effected subsequently by coughing, with fatal hæmoptysis as the result. The present case in some respects resembles one which Dr. Curnow had recorded in the thirty-fourth volume of the Society's Transactions.

The following card specimens were shown:—Mr. Bruce Clark: Unilateral Development of Warty Growths. Dr. F. C. Turner: (1) Circumscribed Superficial Slough of Stomach; (2) Renal Growth invading the Vena Cava. Dr. Chaffey: Tubercular Pyo-salpinx in a child aged four. Mr. D'Arcy Power: Intermuscular Cyst in connexion with Shoulder Joint. Dr. Sharkey: Ulcerative Endocarditis with Embolism of the Left Middle Cerebral Artery, Left Vertebral Artery, Spleen, and Kidney (recent specimen). Dr. G. N. Pitts: Colitis Polyposa, due to Chronic Dysentery and Polypus connected with Meckel's Diverticulum. Mr. Battle: Rupture of Small Intestine (recent). Mr. M. Sheild: Cancer of Stomach.

CLINICAL SOCIETY OF LONDON.

Thrombosis of Basilar Artery.—Insanity after Ovariotomy.—Colotomy with Delayed Opening of the Bowel.

AN ordinary meeting of this Society was held on the 13th inst., Mr. Thomas Bryant, F.R.C.S., President, in the chair.

Dr. CHARLTON BASTIAN read a paper on a case of Thrombosis of the Basilar Artery, with profound coma, extreme lowering of rectal temperature, and death in five hours and a half. A fairly healthy man aged forty-three, having had no previous brain symptoms, was found insensible shortly after the onset of an apoplectic attack, and admitted under his care at University College Hospital at 6 P.M. on Nov. 16th, 1884, in less than one hour. The patient was then profoundly comatose; the breathing was irregular and slightly stertorous; the face was pale, cold, and clammy; all the limbs were flaccid; the pupils were equal and somewhat contracted; there was no conjugate deviation of the eyes; all the reflexes were abolished. There was no cardiac bruit; the heart's action was tumultuous. The rectal temperature at 6.10 P.M. was 98°; at 6.20 P.M. 97°. At 7 P.M. the pulse was 80, fairly full, but irregular in force. The respiration was very irregular—a few rapid breaths, then a pause, followed by a long deep expiration. The rectal temperature was 96·2°. At 7.50 P.M. the rectal temperature was below 95°; the pulse and respiration were nearly as before. The pupils were of the medium size, and quite insensitive to light. At 8.45 P.M. the pulse was 100; the respiration was 17 per minute. At 10.15 P.M. the rectal temperature was still below 95°; the pulse could only be felt with difficulty; it was irregular and at times imperceptible. At 10.45 P.M. death occurred, the rectal temperature having remained below 95° to the end. At the autopsy the basilar artery, in its posterior half, was found to be dilated into a small fusiform aneurysm with thickened walls, and this, together with the middle cerebellar arteries which came off from it, were found to be completely occluded by a soft colourless clot. Other large vessels were pervious and only slightly diseased. The lateral ventricles contained a slight excess of serum, and the veins on their walls were all distended. No lesions were found in any part of the brain. There was no appreciable diminution in the consistence of the pons. The heart was healthy, containing no clots, and no notable disease of the valves—merely some slight thickening. The thoracic aorta showed many raised whitish patches. The lungs were congested and œdematous, and showed hæmorrhagic extravasations into both lower lobes. The other organs were congested and notably tougher than natural. Dr. Bastian pointed out that it was extremely rare for death to take place in less than twelve hours in cases of occlusion of one or other of the cerebral vessels. He had been unable to find any case on record in which it occurred so rapidly as in this instance. In the cases of thrombosis of the basilar artery recorded by Hayem in 1868 death did not take place in less than from sixteen to twenty-one hours. The clinical history of the present case resembles in the closest manner what might be found in a case of large cerebral hæmorrhage. This is seen especially by the great depression of the rectal temperature, which in about two hours and a half from the onset of the attack had sunk below 95°. Last year he had brought before the Society the record of a case of cerebral hæmorrhage in which the temperature in the rectum sank to 94·5°, and where, as in the present case, it continued thus depressed till death occurred three hours afterwards. The fact that thrombosis had occurred in the lower half of the basilar artery, and thus cut off or greatly diminished the supply of blood to the respiratory centre, doubtless accounted for the suddenness with which the fatal issue was brought about. The centres for the third nerve, which are situated at the back of the anterior half of the pons Varolii, seem to have been partially paralysed rather than stimulated. Hence there was not the very contracted condition of pupils which often exists with hæmorrhage into the pons, and has caused such cases to be mistaken at times for instances of opium poisoning. The clinical features presented by thrombosis of the basilar artery vary greatly in different cases, according as the upper or the lower half of the vessel becomes blocked, and also according to the rapidity or slowness with which complete occlusion occurs. The present case afforded a further illustration of the extreme difficulty, or even impossibility, in some cases, of making a positive diagnosis between cerebral hæmorrhage and thrombotic occlusion of some large cerebral artery. Still, in no other artery except the basilar would such occlusion be at all likely to reduce the temperature to such a degree as in the present case. Bourneville never found the rectal temperature reduced below 98° in cases of incipient softening due to occlusion of other vessels. Lesions in the pons Varolii are altogether exceptional in the remarkable amount of variation which they may cause in the general temperature of the body. In the present case we have an incipient softening, or the conditions leading to such a lesion, depressing the temperature below 95° for some hours, whilst in the terminal stage of softening of the pons, as Dr. Bastian had observed, the temperature might rise as high as 110°.—Dr. HALE WHITE said that the case had some bearing on the question of the existence in the cerebrum of inhibitory centres controlling the formation of heat in the body. Physiologists had located this heat centre somewhere about the fissure of Rolando on each side. In cases of lesions of the pons the temperature varied; he had found that in four-fifths of the cases the temperature was lowered; though these examples tended to oppose the view advocated, yet they might be brought into harmony with other facts. The lesion in Dr. Bastian's case was undoubtedly severe, and shock may fairly be credited with the causation of the lowering of the temperature. Bourneville found that the premonitory fall was greatest in those cases where the hæmorrhage was most extensive.—Dr. MARKHAM SKERRITT narrated the

case of a female servant aged twenty-six who was supposed to be suffering from valvular disease of the heart and hysteria. The speech was rather thick when she was first seen; the pulse, respiration, and temperature were normal. The following day the patient was insensible. The temperature was 104°, sweating was profuse, and the surface of the body was dusky and pallid. There was no albuminuria and no sugar in the urine; a few hours later the temperature further rose to 106°, and the patient died in a state of profound coma with rapid fluttering pulse. At the autopsy the heart was found to be perfectly healthy; the basilar and arteries of the circle of Willis were found to be obstructed almost throughout their entire extent.—Dr. EWART suggested that the fall in temperature might be a secondary result of the fall in the number of respirations, and if so, the case could hardly be regarded as one tending to prove the existence of a heat centre.—Dr. BASTIAN, in reply, said that the fall in temperature was produced, he believed, after the manner of shock, and just as occurred in large cerebral hæmorrhages. The shock would be greater because such important parts were cut off from their blood-supply. In more chronic cases of disease of the pons the cutting off of some restraining influences might allow of the production of hyperpyrexia. The view referred to by Dr. Hale White seemed corroborated by a case of apoplexy which had been recently under his (Dr. Bastian's) care. The right hemisphere, was the seat of a hæmorrhage, which increased during the time the patient was under observation; there must have been some pressure within the skull, for there was considerable flattening of the convolutions, more especially on the right side and about the parietal convolution. At first, and as was usually the case in cerebral hæmorrhage, the temperature was found to be lower on the paralysed side of the body. Within eight hours of the onset of the apoplexy the temperature of the body, which had been very low, began to rise rapidly, and the temperature on the paralysed side then became higher than that on the side of the body which was not paralysed. It would be a question to be solved in future cases, but it must not be forgotten that the existence of heat centres about the fissure of Rolando had by no means been clearly established.

Mr. R. BARWELL read a paper on Insanity after Ovariotomy. At the latter end of last October Mr. Barwell removed the left ovary of an unmarried woman aged twenty-nine. The local results were perfect; but certain sequelæ ensued which have not hitherto been recorded. On questioning other surgeons, however, Mr. Barwell found the event not to be isolated, and notably that Dr. Keith, Mr. Thornton, Mr. Dent, and others had met with a like complication. The patient was of fair complexion and mobile temperament, and was admitted into Charing-cross Hospital under the care of Dr. Black. In his absence Dr. A. Routh had charge of the case, and, consulting with Mr. Barwell, it was agreed that ovariotomy should be performed. On Oct. 28th Mr. Barwell removed the left ovary, first withdrawing twenty-three pints of fluid; the pedicle was tied with silk, and allowed to fall back into the abdomen. The usual mode of suture was employed. During the three subsequent days menstruation recurred, and some hæmaturia was observed; it then ceased. On the third day the thermometer stood for two hours at 102·4°, but, with this exception, she never had any fever. The deep sutures were removed after forty-eight hours; the abdominal wound was healed on Nov. 2nd; there was hardly any tenderness in the left groin or elsewhere. The patient, who was naturally very docile and amenable, showed on Nov. 3rd a contradictory and irritable temper; on the 5th—that is, the eighth day after the operation—this had developed into insanity. She was so violent on the 7th that she had to be secured, and this could only be effected by giving chloroform. A subcutaneous injection of morphia (four minims) only calmed her for three hours. With various phases of comparative violence and calmness, but with incessant talking, the patient continued insane, sleeping only in short snatches about two hours out of the twenty-four until the 19th. She then began to show signs of amelioration, especially in saying that she knew she was mad. On the 21st Mr. Barwell ordered an ice-bag to the head, after this she slept more, and gradually improved; on the 28th she could be pronounced sane. During all December she was well enough to take walks, but was for various reasons kept under supervision till December 29th, when she was discharged in perfect mental and bodily health. In spite of several attacks of violence and of struggling, the abdominal cicatrix had held well, and there was no sign of hernia, nevertheless it was thought prudent to provide her with a belt. Several views can, of course, be taken of this case. 1. That there may have been hereditary tendency to insanity. 2. That insanity may follow any of the major operations, ovariotomy not more than any other. 3. That it was the result of disturbance of the urinary organs. 4. That it was the result of disturbance of the generative organs. 5. That it was mere coincidence. 1. Great pains were taken to find any trace of mental disturbance in the patient's family. None could be discovered. Her father died of cerebral apoplexy at an advanced age. 2. If insanity be an occasional sequela of surgical operations, the fact is not well known, nor is it mentioned in surgical writings. 3. The amount of blood lost by the kidney, if any, was insufficient to produce grave effects. Hæmaturia is not uncommon after intra-peritoneal operations performed under a carbolic spray. 4. Although disturbance of the generative organs appears at first sight to offer the easiest explanation, it must be noted that the sort of insanity was not of the kind usually associated with abnormal states of that system. Perhaps some may see an analogy between puerperal insanity and mental disturbance in this case. 5. Mere coincidence might be justly considered the best way of accounting for insanity thus following ovariotomy, if this were an isolated instance.—Mr. THOMAS BRYANT said that a few years ago Mr. Lawson Tait had referred to the development of symptoms of mania after the operation of ovariotomy and during the convalescence. He had had two cases of the kind, and recovery ensued in both. There was no family history of insanity and no urinary trouble. He could not help thinking that there was some connexion between the mania and the operation of ovariotomy.—Mr. ALBAN DORAN said that he had seen a young woman aged twenty from whom both ovaries had been removed. Acute mania came on three weeks after the operation, and lasted eight months without improvement. In cases of chronic ovaritis the patient might become demented; the chief symptoms were sluggishness and selfishness, and not those of an erotic kind.—Mr. MEREDITH said that it would probably be found that many cases of mania had occurred after ovariotomy; the insanity usually set in within a week of the operation. He spoke of the case of a single woman aged fifty-four from whom he had removed a large tumour weighing 7 lb.; it had many adhesions. All went well till the wound was healed. Acute melancholia suddenly set in about a month after the operation; the affection lasted for two months. There was no urinary trouble. He had an impression that mania had followed amputation of the breast.—Dr. EDIS thought that, looking at the serious nature of the operation, and regarding the extremely nervous and mobile temperament of the patient, who was thus in a high state of nerve tension, the occurrence of mania was not to be wondered at. He narrated the case of a yeoman farmer's wife who was naturally of a dull temperament, and who a few days after ovariotomy suffered from melancholia, which lasted about ten days.—Dr. F. L. BENHAM said that the nature of puerperal insanity was still unexplained. It was possible that the insanity after ovariotomy and puerperal insanity were dependent on similar causes.—Dr. BLANDFORD said that he could not say whether interference with the genital organs had anything to do with causing the mania, but the circumstances which attend the operation of ovariotomy are such as might induce insanity in psychical subjects. The young woman knew that a severe operation was to be performed; she was kept in bed with the bowels confined by the influence of a powerful drug like opium—such conditions might originate insanity. He did not think that the kidneys had anything to do with the occurrence of the mania, though Sir James Simpson had regarded albuminuria as the cause of puerperal insanity.—Mr. BARWELL, in reply, thought that even if the occurrence of mania after ovariotomy were relatively common, yet the fact does not seem to have been sufficiently recognised.

Mr. DAVIES COLLEY read the notes of three cases of Colotomy with delayed opening of the Intestine, in which after the bowel had been found by the usual operation for left lumbar colotomy, he had delayed opening it for one, four, and six days respectively. He considered that in the ordinary mode of operating there was considerable risk of peritonitis, or of suppuration in the planes of connective tissue in the vicinity of the colon, and that these dangers were much diminished by delaying the opening of the bowel until the deeper part of the wound had had time to be sealed by reparative processes. This plan had previously

been adopted at Guy's Hospital by Mr. Howse with successful results. The chief difficulty was to find out a mode of securing the protruding bowel in such a way as to avoid the extravasation of its contents or the strangulation of its walls. He had found that this could be satisfactorily effected by means of a clamp consisting of two steel bars, upon which were placed rounded ivory studs, about half an inch apart. Upon approximating the steel bars by means of screws near their extremities, the two pairs of ivory studs could be made to hold the coats of the bowel at two points. At the first dressing the screws should be relaxed, or the clamp might be altogether removed. By adopting this plan in two of the cases, rapid repair had followed, and there had been very little constitutional disturbance. In many cases in which the operation had to be performed on account of intestinal obstruction, it was obvious that this delayed opening of the bowel was not practicable. Mr. Davies Colley further submitted that a similar plan might be desirable in cases of tumour of the large intestine. The loop containing the growth might be left protruding from the wound for a few days, and then removed by the knife, cautery, or some caustic agent. Again, it might be expedient in cases of colotomy to draw out a complete loop containing the whole calibre of the colon, and to remove this loop after an interval of a few days. In this way the operation would ensure a perfect artificial anus, for the opening would then be the terminus, and not merely a lateral outlet of the intestinal tract.—Mr. BRYANT agreed almost entirely with the method advocated by Mr. Davies Colley. The method greatly diminished dangers arising from wounding the peritoneum. It was the escape of fæces into the peritoneum that excited peritonitis, and if the surgeon left the bowel alone until adhesions had formed, the risk would be considerably diminished. In performing colotomy by this method, he believed it to be a good plan to draw more of the bowel out of the wound than even Mr. Davies Colley had done. It was the passage of fæces through or past the lower opening that should be done away with, thereby removing the irritation to which the diseased bowel was exposed. If this were done the disease ceased to grow, and might even disappear altogether. This method of pulling out a knuckle of the bowel could be done in about half the number of cases of colotomy, and as much as three or even four inches of the bowel could be drawn out. Then at a later date, when the operator pleased, the bowel could be opened without risk.—Mr. HOWSE said that in his earlier cases he used a wire or suture, which transfixed the whole of the coat of the intestine in the same way as he had done in gastrostomy. But the nutrition of the colon was much less perfect than that of the stomach, and the risk of extravasation from the giving way of the suture in the bowel was greater. Later on he adopted other methods of fixing the intestine, and an old torsion forceps, which had lost its "biting" powers, was used, a thin india-rubber tube being passed over the blades and over the wedge of the forceps. By using these forceps to fix the bowel to the skin the risks of sloughing were much diminished. The forceps could be removed at the end of forty-eight hours, or on the third day. The bowel should be opened by as small an incision as possible; an opening sufficient to allow of the passage of a No. 8 catheter was large enough. He had employed this method recently in a case of intestinal obstruction, where the distension from accumulated gas was easily relieved. The possibility of colectomy referred to by Mr. Davies Colley could be accomplished by drawing out a complete loop of the intestine at the time of the operation. Later on it would be found difficult to excise the bowel, as he had considerable trouble in distinguishing the intestine from the surrounding structures, and, further, the structures become softened by inflammatory action; the removal must therefore be done earlier.—Mr. H. CRIPPS considered that the method advocated necessarily complicated the operation, which had better, he thought, be done at one sitting. There were two chief dangers in colotomy; the first was opening the peritoneum, and the second damaging the subperitoneal fat in the search for the bowel. He made reference to a simple procedure which was not available in cases of complete obstruction. It was an empty bowel which gave rise to so much disturbance, and he suggested, as others had done before him, that a No. 7 catheter should be passed per anum through the rectal stricture, and a Higginson's syringe attached by means of a soft indiarubber tube; inflation by this means makes the bowel rise in the wound precisely at that part which is uncovered by peritoneum.—Mr. DAVIES COLLEY, in reply, said that it was Mr. Howse's employment of the torsion forceps that gave him the idea of using the clamp. With regard to the performance of colectomy, he wished to say that it was at the first operation that the whole of the diseased intestine should be drawn out of the wound, the excision to take place later on. He could not agree that the operation of colotomy was really complicated.

The following living specimens were shown:—Mr. Charles Stonham: A successful case of Gastrostomy one month after the operation, which was performed on account of malignant disease of the pharynx. Mr. Macnamara: A case of Wiring the Fractured Olecranon, and another of Wiring the Fractured Patella. Mr. R. J. Godlee: A case of Empyema in a boy with much deformity of the chest. Dr. Hadden: A case of Obliterative Disease of Arteries and Veins. Dr. Coode Adams: A case of Psoriasis and Hemiplegia.

MEDICAL SOCIETY OF LONDON.

The Constitutional Treatment of Diseases of the Uterus and its Appendages.

AN ordinary meeting of this Society was held on the 16th inst., Dr. W. Miller Ord, President, in the chair.

Dr. C. H. ROUTH read a paper on the Constitutional Treatment of Diseases of the Uterus and its Appendages. He began by quoting several passages from Dr. Clifford Allbutt's Gulstonian Lectures, which referred to the not infrequent practice of gynæcologists of over-treating the uterus and neighbouring organs. He said that the cause of his reading the present paper was the result of the impression he had gained from a perusal of the Gulstonian Lectures of last year, to the effect that Dr. Allbutt had brought unfounded charges against gynæcologists. He admitted in the course of his paper that the neurotic element was a most important factor, but considered that many cases in which the neurosis was alleged to be the sole complaint there was danger in overlooking the uterine disorder. He spoke of the case of a virgin who suffered from gastrodynia and emaciation, which had been treated as one of primary nerve disorder, but which was found to be attended with prolonged leucorrhœa, and in which he had found uterine erosion. This case had been treated by a physician who had never examined the generative organs. Again, in certain cases of displacement of the uterus associated with headache and backache, and in which the patient was invalided and almost confined to bed for a period of many months, the symptoms were promptly relieved by rectification of the uterine displacement. Many cases bearing out his views were narrated, and the general conclusion was drawn that physical examination of the generative organs was decidedly neglected by many physicians and general practitioners. Reference was made to a case of cancer which had come under his care, and which had been previously overlooked for the simple reason that no vaginal examination had been made, the doctor in charge putting the patient's symptoms down to "change of life." In other cases of this kind he had detected a large number of mucous polypi, the removal of which led to the cure of the patient. The case of a lady, who suffered from severe metrorrhagia and many nervous symptoms, was shown to be due to the presence of fibroid growths in the uterus, treatment directed against which was also followed by a return of the patient to health. The failure to treat the local disease was therefore a source of much suffering to the patient, who was regarded as being the subject of a neurosis, to be cured by constitutional means. Cases of insanity were often dependent, in his opinion, on diseased conditions of the womb, and the case of a lady who was insane, and in whom an ulcer of the womb existed, was related; the insanity passed away and recovery ensued after local treatment of the uterine ulcer. He was not an advocate for frequent clitoridectomy, but he thought there were a few cases in which this operation would prove beneficial. Again, cases of hydro- and pyo-salpinx were not unfrequently overlooked by the physician, who treated the nervous symptoms without even recognising the existence of such local diseases. He concluded by stating that gynæcologists did not neglect constitutional treatment, but combined this treatment with proper local applications.

Dr. ORD said that Dr. Routh's paper chiefly dealt with the question of the necessity of a thorough examination of the

generative organs. It raised questions as to whether visceral and other neuroses might be due to uterine disease or not.

Dr. ALLBUTT said that he had been warned to expect an attack, but Dr. Routh's paper could scarcely be called an attack, seeing that he was entirely in agreement with the general tone of the paper. He said that his point was not that the uterus is not subject to local disease, but that it may sometimes be involved in disease as the result of a general affection. The uterus is like the heart, full of nervous and vascular connexions which bring it into relation with the rest of the body. Palpitation and pains about the heart may occur not as a result of disease of the heart itself, and so it was sometimes with the uterus. If a patient suffering from cardiac disorder due to disturbance elsewhere were told that his heart was diseased, it is probable that a grave hypochondriasis would develop, and so it was with women who were told that their uterus was diseased; the uterus was an organ hidden from a woman's observation, and there was more or less mystery attached to it, and if the patient were told that her womb was the seat of all kinds of horrible disease, she would be led to believe that she was in a very bad way and the mind would be correspondingly depressed; in fact, she would have the "arrow of hypochondriasis implanted in her heart." Whilst he admitted that there were primary diseases of the uterus, yet he believed that this was not always the case, and that women might suffer from nervous symptoms which were no more due to the uterus than were such symptoms when they occurred in man. Women, like men, were subject to neuroses of various kinds. Disease of the uterus, slight in itself, may set up severe nervous disorder which gradually overshadowed the original mischief, and may remain even after the local trouble had ceased. This kind of thing was admitted by all. It was most necessary, therefore, that the whole history of a case should be ascertained. In some cases it was difficult to make out which was or was not the "first stone thrown into the pond," but in his opinion in many cases the uterus is secondarily affected. He believed that many functional disorders, and some of the lighter kinds of structural changes, could be caused as the result of a primary neurasthenia. Such cases were sometimes treated as uterine from first to last. He had seen many cases which the gynæcologists had failed to cure with their local treatment, and no doubt these would balance with those cases which the physician had not, and the gynæcologist had, succeeded in relieving. It was for what he would call "the jury of the medical public" to decide between them. He admitted freely that there were a large number of cases in which the uterus was primarily diseased. With regard to the case of masturbation referred to by Dr. Routh, he thought that it cut both ways. It was open for him to say that it was the inherited neurotic taint that gave rise to the masturbation and other symptoms, that the masturbation was the flower and consequence of the nervous disease. He could not allow himself to be classed amongst the obscurantists, and he believed he had on every possible occasion admitted the great advances in medicine which the gynæcologists had made as the result of careful and necessary physical examination. He really counted Dr. Routh and Dr. Playfair as his allies, and referred in terms of approbation to the Weir-Mitchell treatment of neurasthenia which Dr. Playfair had so powerfully advocated.

Dr. PLAYFAIR said that he considered Dr. Allbutt's lectures had been chiefly directed against over-treatment of the uterus and to the mischievous effect which such over-treatment caused. There could be no doubt that sometimes neurotic affections became dominant and overshadowed the original uterine disorder. With regard to the necessity for physical examination, so strongly urged by Dr. Routh, he thought it was trying to prove what had already been demonstrated. He felt sure that great good would arise from the discussion of the paper, as it had enabled Dr. Allbutt to restate his views.

Dr. ROBERT BARNES maintained that the gynæcologist was not a specialist, for he followed the excellent advice of interrogating the whole of the functions of the body. In order to investigate the condition of all the organs there must be an application of the means of physical examination to every part, and the generative organs should be included in the investigation. He could not agree that a primary neurosis could set up disease of the uterus except in a very problematical way. The heart was a "responsive" organ and influenced by emotions and other disturbances everywhere occurring, but we could not say the same of the uterus. He was glad to find that he was so much in harmony with the views of Dr. Allbutt.

Dr. W. DUNCAN considered that Dr. Allbutt had "hit the right nail on the head" when he denounced frequent uterine examinations. In cases of slight erosion of the womb or of endocervical catarrh the neurotic symptoms were out of all proportion to the disease, and so it was with flexions of the uterus. He found that general treatment directed against the neurotic condition was followed by cure; the local treatment should be of the simplest, and he deprecated anything like frequent examinations.

Dr. GRAILY HEWITT congratulated Dr. Routh on his paper and on the effect of it; for he confessed that a perusal of Dr. Allbutt's lectures had led him to believe that Dr. Allbutt discouraged treatment directed to the uterus, and now it was obvious that such was not the case. He had the fullest confidence in the Weir-Mitchell treatment, and he had given an introductory lecture some years ago at University College on this subject. He considered that constitutional treatment was most important, and that it went behind the other treatment. The omission of this element of treatment was, in his opinion, so frequent because of defective physiological education in reference to the elementary laws of the nutrition of the body. Those gynæcologists who paid no attention to the occurrence of displacements and alterations in shape of the uterus were those who paid no heed to the maintenance of the nutrition of the system.

Dr. HEYWOOD SMITH, Dr. WYNN WILLIAMS, and Dr. ROGERS joined in the discussion.

The PRESIDENT said that in the Gulstonian Lectures Dr. Allbutt had not attacked the principle of physical examination, but he had questioned the validity of some methods of uterine treatment.

Dr. ROUTH briefly replied.

OBSTETRICAL SOCIETY OF LONDON.

Extirpation of the Uterus for Cancer.

A MEETING of this Society was held on Wednesday, March 4th, J. B. Potter, M.D., F.R.C.P., President, in the chair.

The following specimens were shown:—Dr. Galabin: Uterus of an old woman with Cavity distended, from partial Obstruction by a Septum in the lower part of the Cervix and upper part of the Vagina. Mr. Walter Griffith: Menstruating Uterus. Dr. Herman: Uterus inverted from relative Shortness of the Cord.

The PRESIDENT delivered the annual address.

The adjourned discussion on Dr. W. Duncan's paper on Extirpation of the Uterus for Cancer was resumed by Sir SPENCER WELLS, who said that he thought the previous speakers had been too decidedly adverse to the principle of the operation, especially Mr. Thornton, who condemned not only excision of the uterus, but also the use of the curette, and would limit surgical treatment to amputation of the cervix and the use of chloride of zinc. Mr. Doran's remarks on the arrangement of the lymphatics tended the same way, implying the fear that, even in the early stages, the disease may have passed beyond the possibility of removal. Dr. Playfair condemned the operation utterly, referring to the uncertainty of the diagnosis till it was too late, and preferring Sims's operation (amputation followed by chloride of zinc) to extirpation, on the ground that it affords as much relief at a much smaller risk. He traversed Dr. Playfair's statement about his (Sir Spencer Wells) case of extirpation of the cancerous uterus, "that if the patient had been let alone or Sims's operation done, her expectancy of life would have been as good, to say nothing of the risks of the operation." The fact was that this treatment had been tried and failed, and the operation was done after it had failed to relieve pain or discharge, and after careful consultation as to the risks of inducing premature labour. The immediate result of the operation had been satisfactory, and great relief had followed for some months before the disease returned, which ended fatally in a year. In some cases, no doubt, chloride of zinc, or bromine, or chromic acid, or the actual cautery (if the patient is not pregnant) may lead to arrest of the growth for a year or more; but in most cases no more good, perhaps less good, is done than by simpler applications. He showed a specimen of the

result of Sims's treatment carried out by Sims himself. He scraped away all the diseased tissue with the greatest care, applied chloride of zinc, and the slough which came away represented nearly the whole uterus; the patient lived only four months afterwards, and suffered as much as if no treatment had been pursued. He then compared amputation of the cancerous cervix to partial removal of a cancerous breast, and maintained that if Sir James Paget was not aware of a single case of recovery (i.e., survival for ten years without any active return) after amputation of the breast, and yet operated in cases of cancer of the breast, we are justified in performing extirpation of the entire uterus even if no better result followed. Again, the results of Olshausen and Schroeder lead us to think that improved methods of operating may give us better results in the future. There is still much to learn in the details of the operation, and improvement both in early diagnosis and early operation may give a much lower mortality, retarded return, or even complete recovery. He trusted that condemnation of the operation may not be the verdict of the Obstetrical Society.—Dr. PRIESTLEY believed that statistics underrated the frequency of cancer, and that it was commoner in some places than in others. The disease was so terrible that all new operations should be considered with an earnest desire for their success. The two questions to be answered about extirpation of the uterus for cancer were those of immediate recovery and return of the disease. The answer to the first question was at present hardly satisfactory, nor was that to the second. With regard to Dr. John Williams' statement—that operation sometimes assisted the spread of the disease, by removing tissues which would have impeded its progress for some time and enabling it to attack deep parts earlier than it would if left alone,—he thought this happened in some cases. He therefore did not, under present conditions, advocate the operation of extirpation of the uterus for cancer. He mentioned a case in which a tumour had been removed from the cervix last summer, so skilfully that the cervix seemed almost natural enough to justify a verdict of mistaken diagnosis; within three weeks the disease returned and soon attacked the vagina, but the patient was still alive and in comparative comfort, simply from the use of palliatives consisting of tannin, sulphate of zinc, and iodoform in powder. The suitable cases for operative interference were those of early cancer of the cervix, in which total removal of the disease seemed possible. Some such cases remained free from disease for many years. Possibly in some more advanced cases removal of all within reach, followed by palliatives, might be justifiable; other cases he was disposed to leave alone. He thought that the mental distress of a patient about to undergo an operation should be remembered. He did not despair of the discovery of some remedy for cancer, especially since the latest observations on tubercle, which had some sort of pathological relation to cancer.—Dr. GRAILY HEWITT agreed that statistics are at present insufficient to determine the value of extirpation of the uterus for cancer. Removal of the cervix for epithelioma was an unquestionably valuable operation, but the treatment of cases in which disease had spread higher up was still doubtful. He had shared the responsibility of advising extirpation in Sir Spencer Wells' case, and thought that the result justified the opinion given. It must be remembered that the patient was pregnant, and that extirpation of the gravid uterus had not then (three years and a half ago), so far as was known, been performed. All experience justified the removal of cancer whenever possible. He insisted on the necessity of early diagnosis; in most cases the disease has obtained a firm hold before its presence is suspected.—Dr. GALABIN said that the majority of the speakers agreed with the view that in ordinary cases of cancer of the cervix the uterus should not be extirpated. This view, which was arrived at by the author of the paper after the performance of two operations, was that which Dr. Galabin had always held so firmly that he had always been opposed to the operation, and had neither performed nor advised it. Cancer of the cervix might begin anywhere, but in the majority of cases it began near the os externum, thence it ascended the cervical canal so far that slicing off the cervix with an écraseur almost always left some of the growth behind on the surface of the canal; but it spread even more rapidly over the vaginal cervix, and when the uterus was extirpated, the line of section would be nearest the growth at the surface of the vagina. It was not shown that in total extirpation any wider margin could be given than in supra-vaginal amputation, which operation could be done even when the disease had reached the vagina, and even if it were necessary to open the pouch of Douglas, this operation would still be less dangerous than total extirpation. His experience of chloride of zinc had been more favourable than that of Sir Spencer Wells. He did not excise the disease piecemeal, but all at once, and applied the chloride of zinc ten to fourteen days later. He generally found the line of section pass clear of all manifest disease. But in several cases in which this was not so, and the operation was therefore obviously inadequate, the results of the whole procedure had been good. In two cases the patients had returned after more than two years without any recurrence of the growth, but with retention of menstrual fluid from occlusion of the canal. As regards the chance of eradication, he did not think cancer of the uterus could be compared with cancer of the breast, which was generally carcinoma. In the cervix it was (in his experience) epithelioma at first, rapidly lapsing into medullary carcinoma. Cancer of the body was generally cylinder epithelioma at first. He thought there was greater chance of eradicating an epithelioma than a carcinoma. In cancer of the body he thought extirpation of the uterus was justifiable. The diagnosis, though difficult, was quite possible in the early stage, from examination of a fragment, to one accustomed to the healthy and morbid appearances of the uterine mucous membrane. He had had no ill consequences (such as those feared by Mr. Thornton) from the use of the curette. He generally used the blunt curette, which only removed prominent or superficial portions. In one case after curetting and the application of nitric acid to the cavity the patient improved so much that a mistake in diagnosis was suspected by the medical attendant. After a time, however, the disease returned.—Dr. EDIS thought that vaginal extirpation of the uterus was justified by a mortality of 28·6 per cent., which was no greater than that of ovariotomy in the early days. The mortality of supra-vaginal amputation was only 7·25 per cent., and the tendency to recurrence apparently no greater than in complete extirpation. Early diagnosis was a great desideratum; either patients failed to present themselves for examination, or their medical advisers put off consultation with experts till too late. Patients preferred operation to a lingering and hopeless disease. With our present limited knowledge, we could not assert that extirpation of the uterus for cancer was unjustifiable, if undertaken early enough.—Dr. W. DUNCAN said that he hoped the result of the debate would be to put an end to extirpation of the uterus for cancer of the cervix. Had he known the papers of Ruge and Veit on the pathology of the subject, he would not have performed his first case. In cancer of the body he considered the operation justifiable, and the curette was a valuable means of diagnosis, while he had not found any ill consequences follow its use. He did not believe that the mortality of extirpation will ever be as low as that of supra-vaginal amputation.

Reviews and Notices of Books.

On Renal and Urinary Affections. Part III. Miscellaneous Affections of the Kidneys and Urine. By W. HOWSHIP DICKINSON, M.D. Cantab., F.R.C.P. Lond. London: Longmans and Co.

ELEVEN years have elapsed since the first part of Dr. Dickinson's work "On Renal and Urinary Affections" was given to the profession. That, it will be remembered, was solely devoted to the consideration of Diabetes, whilst the second part dealt with those affections of the kidneys commonly known under the collective clinical term of "Bright's disease." The present volume, which completes the work, treats of the more general renal affections, such as suppurative nephritis, malignant and scrofulous disease of the kidney, stone and gravel, chyluria, hæmoglobinuria, phosphaturia, and functional albuminuria. If Dr. Dickinson's work were to be regarded as a systematic treatise, the want of logical arrangement of the different parts would no doubt cause inconvenience and some confusion to the reader; but regarded as a series of separate essays, the disjointed parts, with the help of a comprehensive index, fall together without

the reader feeling, to any great extent, the want of association. The fact, however, that it has taken eleven years to complete the work serves to strengthen the assertion we have previously advanced, that with the present rapidly advancing state of medical knowledge the age for the production of large treatises is past; for before an author has time fairly to master the literature of his subject, in itself a gigantic task, and arrange the details of his work, new discoveries necessitate a revision of much that he has already completed. Dr. Dickinson has undoubtedly solved a part of this difficulty by dividing his work into a series of monographs, but even here the obvious objection arises that whilst the last volume represents our latest knowledge on the subjects of which it treats, the first and second undoubtedly require considerable revision to bring them up to the same level.

In the present volume the essay on Renal Calculus deserves the first place for consideration. It is undoubtedly the most complete description extant of this formidable and painful affection. The etiology, structure, classification, symptoms, and treatment, are all fully detailed. The author is evidently no great believer in the solvent treatment of renal calculi, as advocated by Dr. Roberts; and this negative attitude is justified by the experience of the past, for in the days when solvents were largely used physicians pointed out that while good results were often obtained with vesical, the administration of solvents in the case of renal, calculi was nearly always futile. The reason of this lies in the fact that in the bladder it is possible to keep the stone always surrounded with alkaline urine, whilst in the kidney the action of the solvent is only partial and temporary. Dr. Dickinson does not allude to the possibility of causing encystment of the calculus by keeping the patient at rest, in one position, as much as possible. In cases where the calculus is tolerably large and an operation not advisable, this plan may be adopted with advantage. In one case which came under our observation it proved a complete success; and the fact that calculi are found thus encysted post mortem, in persons who have suffered but little during life, ought to encourage us to give the plan a fair trial. Speaking of pyelitis, the author criticises the statement of Roberts, that the very irregular, spindle-shaped epithelium shed affords "certain evidence of its origin," and maintains that epithelium of like character is derived from other parts of the urinary tract besides the pelvis. In this we quite agree with Dr. Dickinson, for we are sure that no positive conclusion as to its place of origin in the urinary tract can be drawn from the appearance of this epithelium, and the part of the urinary tract it is derived from can only be determined by other clinical indications.

In the section devoted to the consideration of Malignant Tumours the writer incidentally brings forward a very important question—viz., Which kidney is the more frequently attacked? Thus Roberts found in sixty unilateral cases each kidney affected an equal number of times. Ebstein, on the other hand, states that the right is attacked oftener than the left, in the ratio of thirty-one to twenty-three, whilst Dr. Dickinson found eleven belonging to the left side and only one belonging to the right. Our own experience is in accord with that of Dr. Dickinson; indeed, so frequently have we found the left kidney affected—as regards not only malignant, but other unilateral affections of that organ,—that we have considered whether the selection is altogether accidental, or if there may not be some as yet undetermined cause for the preference.

It would be impossible for us, with the space at our command, to notice all the good features of the work before us; but after the chapters on Renal Calculus, those on Hæmoglobinuria and Chyluria deserve special study and attention. We should, however, fail in our duty if after such commendation we omitted to point out those parts of the work which in our opinion fall short of existing knowledge on the subject. In the first place, we regret to find in the section on "surgical kidney" no reference is made to Mr. Beck's invaluable clinical and pathological researches nor can there be any excuse for the omission, since it is now six years since they were published in "Reynolds s System of Medicine," and have been generally accepted, as is shown by their having formed the basis for further investigations, and also by their having been adopted by most writers on pathology. The author no doubt differs from Mr. Beck, but, in omitting to reply to or notice views contrary to his own, Dr. Dickinson tacitly admits, we think, that they are unanswerable. Nor has he done full justice to the subject of phosphaturia. Although he speaks of the condition as "phosphuria," implying thereby that unoxidised phosphorus, as lecithin, glycerine, phosphoric acid, &c., may pass into the urine, he makes no allusion to that now well-ascertained fact, nor the conditions of the nervous system in which it has been noticed. Nor, even when speaking of the elimination of phosphates, does he refer to the numerous facts recently determined, chiefly by German observers, with regard to the relative elimination of nitrogen and phosphoric acid under different conditions of metabolism. Again, the important clinical fact, that certain pathological states are characterised by a decided diminution of phosphorus in the urine, is not mentioned; as, for instance, Gee's observation as to the almost complete disappearance of the phosphates from the urine in ague, and the similar observation that has been made as regards scurvy, and after the administration of certain medicines, such as bromide of potassium, &c. All these points ought to have received attention, since it is alone by the study of them that we can hope to get an insight into the nature of the tissue changes occurring under pathological conditions. Apart from these objections, we must congratulate Dr. Dickinson on the high quality of his work throughout; it is that of a scholar, a scientific physician, and a clinical teacher, and will for long hold its place as a classic treatise on the subject of which it treats. Nor, whilst awarding this high degree of praise to the text, must we forget to mention the very admirable engravings that illustrate it.

THE SHOEBURYNESS EXPLOSION.

THE following is a description of the fatal injuries incurred by the officers who lost their lives by the recent sad accident at Shoeburyness:—

Colonel Fox Strangways: Laceration of right foot, part of great toe blown away, compound comminuted fracture of both legs. Amputation of both legs was performed by Sir W. Mac Cormac after midnight. Death from shock before 8 A.M. the next morning.

Colonel Lyon: Both legs completely smashed, great shock. Amputation of both legs immediately performed by Mr. Deeping and Mr. Jones. Death from shock about 8 A.M. next morning.

Sergeant-Major Daykin: Compound comminuted fracture of left leg, involving the knee-joint. Amputation at the middle of thigh by Mr. Jones. There was also severe chest injury. Death from shock next morning.

Gunner Underwood: Compound comminuted fracture of right thigh. Amputation by Mr. Morris. Death from shock next morning.

Gunner Allen: Right leg blown away from below knee, lacerated wounds under chin and on side of throat. Killed on the spot from profound shock.

Mr. Rance: Large lacerated wound in the middle of both thighs, wound under left knee crushing the tibia, the fragments of shell passing backwards and downwards and coming out through the lower part of the calf. Shock and depression so great that no operative interference was resorted to. Died from exhaustion on the ninth day.

Colonel Betty and the officers of the garrison, Shoeburyness, have sent a letter of thanks to the medical men who rendered aid to the sufferers by the explosion, Messrs. Deeping, Phillips, Morris, and Jones, and have requested them to consider themselves perpetual honorary members of the Royal Artillery Mess, Shoeburyness.

THE LANCET.

LONDON: SATURDAY, MARCH 21, 1885.

A VERY important paper has just been issued by the Director-General of the Army Medical Department, entitled "Sanitary, Medical, and other Notes and Memoranda for the information of the Principal Medical, Sanitary, and other Officers of the Army Medical Staff of the Suakim Expeditionary Force." It bears evidence of a careful study of the subject, a thorough practical knowledge of the requirements of the troops on active service, an ample and judicious provision for their wants, and some excellent hints for the guidance of the medical officers. The notes are already so condensed that it is impossible to give a summary of them on all the points treated; we shall therefore content ourselves with noticing a few of the more important.

A detail is given of the hospital accommodation which is to be provided under the three classes of base hospital, floating hospital, and field hospitals; and the hospital at Suez will also be available for the reception of cases. A staff of nurses will be provided for the base, floating, and Suez hospitals. Full instructions are given for sanitation at the ports, on the march, and in camp; for the assistance to be afforded to the wounded in action, for the first dressing on the field, their immediate transport to the field hospital, "where antiseptic surgery and dressing can be skilfully and properly applied once for all," and their removal by a staging system of transport to the stationary hospitals, where "provision can be made for equipment, dieting, clothing, nursing, and, ample supplies of medical and surgical equipment." The subject of water has received due attention, and instructions are given as to the best means of rapidly testing its quality, and, so far as is practicable, ridding it of impurities. Rules are laid down for the conservancy of camps and hospitals, and the disposal of refuse and of dead animals. When there is an early morning march, or the men are employed late at night, it is recommended that a ration of hot cocoa and milk, coffee or tea, should be issued, we presume in addition to the regular ration.

The diseases of which the prevalence may be anticipated are diarrhœa and dysentery, enteric fever, heat fevers, heat exhaustion and sunstroke, and ophthalmia. The two great factors in the production of disease are fatigue and insufficient nourishment. "Climatic conditions are so far secondary to these that they may, to a greater or less extent, be overcome by the avoidance of one, and ample provision for the other." Dust and flies and overcrowding are recognised as the chief causes of ophthalmia, and with a view to its prevention the men are to be encouraged to wear glasses and veils, and overcrowding in tents is to be avoided. As a protection against the effects of the great diurnal ranges of temperature in causing diarrhœa and dysentery, each soldier is to be provided with two flannel belts, and puggarees and back pads (spine protectors) are to be issued to guard the men from the direct solar influence. The remarks on diarrhœa and enteric fever are very judicious, and the necessity for treating all cases of diarrhœa attended with elevated temperature as enteric fever, at least in the first instance, is enforced. "It is to be borne in mind, too, that in actual practice in warm climates, and under the conditions of field service, this fever does not invariably conform to the temperature ranges which have been far too arbitrarily laid down by medical authors, for a fever may be non-conformable to such ranges, and yet be indubitably enteric fever."

The instructions with regard to the "Wounded in Action" appear to us to be perhaps the most valuable portion of the paper, especially as pointing out the danger of officious surgery. "It is a mistake to suppose that much is needed, or can be done, for a wounded man under fire or immediately after an action, except attending to his pressing requirements and moving him carefully to a place of safety, where the necessary time and attention and the results of consultative measures can be applied.....In small wars with semi-civilised nations, like the present expedition, it should be quite practicable to advance a field hospital, or section thereof, together with a portion of a Bearer Company, well to the front—that is, to carry the hospital to the wounded instead of the reverse. Under such circumstances the wounded should be at once transported there without being first subjected to the risk of defilement of the wound by the hurried application of a first dressing, or the displacement to the coagulated blood agglutinating its sides and edges." The first dressing should be of the simplest kind, and ought to consist chiefly in covering the wound, placing the injured part in a suitable position, and when necessary rendering it immovable. The first dressing recommended by Professor LONGMORE consists of carbolised tow, carbolised gauze, bandage, safety-pin, a triangular bandage, a wrapper of tinfoil, and a parchment paper cover impregnated with ½ per cent. of corrosive sublimate, and appears to be well adapted for field service. "The principles of modern surgery are to keep a wound, if possible, aseptic throughout; if this cannot be secured, to make it antiseptic, to keep it in a state of physiological—that is, absolute—rest, and to secure drainage." The method adopted successfully in the Egyptian campaign is described, and instructions given for its application under various circumstances. We concur most fully in the opinion that "all surgery or dressing that has not a definite object in view is meddlesome, and meddlesome surgery or dressing is fatal to the aseptic or antiseptic method."

Ample provision appears to have been made for the sanitation of the force, for the treatment of disease when it occurs, notwithstanding the sanitary precautions, and for the help of the wounded in the field, so far as these arrangements depend upon the Head of the Medical Department. We trust that the military arrangements for supply and transport may be equally judicious, for on them must depend much of the success of the others. As bearing upon this point, the Director-General gives a very judicious caution to the officers of the medical staff:—"In view of the difficulties of transport, medical officers should be impressed with the necessity of having a few well-selected drugs in as concentrated a form as practicable, and they should be cautioned to avoid 'a run' on one drug when others would suffice for the same purpose. The better the medical officer, the fewer will be the drugs he will require

for the efficient treatment of the sick and wounded in the field at the front." The notes and memoranda cannot fail to be most useful to the officers employed in this expedition, and afford gratifying proof of the watchful care of the Head of the Department and the sound judgment evinced in making the necessary professional arrangements. We have but one fault to find with them: they would, in our opinion, have been better adapted for service had they been printed as a pocket manual instead of in the folio form characteristic of War Office documents.

SINCE Sir LYON PLAYFAIR'S celebrated argument in favour of his views of medical reform the question of the numerical strength of the profession has become one of great importance. Though the whole situation of the country and of Parliamentary government scarcely permits us to hope that anything so sensible and reasonable as the Medical Bill of the Government will be passed, yet it is possible that it may be reintroduced, and the worn-out and very poor arguments of last year repeated. Our readers will remember that Sir LYON PLAYFAIR frightened the House of Commons by the appalling picture of a community without sufficient doctors. The argument was, "Be careful *how* you improve medical education; if you overdo your improvements, you will deter young men from entering the profession, and the natural waste of the profession, which is 1600, will not be met by an adequate supply." The argument at best was a bad one from Sir LYON PLAYFAIR. If arguments are to be used for keeping down medical education, they come with ill grace from the representative of an ancient and famous university, whose function ought to be to hold high the standard of medical knowledge. But the argument was not only unworthy of Sir LYON PLAYFAIR. The basis of it was one of sand, as we showed at the time. So far from the waste of the profession being 1600, we proved that, with great pains to ascertain the deaths of medical men when they occur, the indefatigable registrar, Mr. MILLER, cannot succeed in getting evidence of the decease of more than between 500 and 600 in the year, while the names added to the Register are annually over 1200. The new Register confirms the inaccuracy of Sir LYON PLAYFAIR'S representation, from which a very slight acquaintance with the facts of the medical profession would have saved him. It must be patent to anyone who takes any pains to observe that there are many indications of overcrowding in the profession and of unseemly pressure of competition, such as low medical charges and the excessive number of applications for the most ordinary appointments. But a few facts from the Medical Register for 1885, just issued, will give the statistical proof of what is so obvious. In the Register for 1885 there are the names of no less than 25,321 medical men. The average number of names in the Medical Registers for the last four years, and in those for the four years preceding the last, are respectively 24,228 and 22,723, or a difference of 1505 per year in the last four years. The number in the Register for the present year is 25,321, as against 24,517 the year before, or 804 more. We have said that the ascertained loss of the profession by death is between 500 and 600. Taking an average of nine years the annual number of ascertained deaths is 572·5. Of course, there are other ways in which practitioners are lost to the public, as by retirement. But these must be comparatively few. Let us now place clearly before our readers the new registrations. In the last year the new registrations were in England 769, in Scotland 381, and in Ireland 238, making a total of 1388. In the year 1883 there was a total of 1304. The average annual additions to the Register, or new registrations, for the last four years were 1229, as against the average of 1013 in the four years preceding these. We need not say more to prove that there is nothing in the supply of medical men to make the Legislature hesitate in raising a little higher the standard of medical education, while there is much in the facts we have adduced to make young men ponder before they enter a profession already overcrowded.

Table F, from which we have quoted these interesting facts, is only one of a number of tables which, with all the Medical Acts of Parliament and other information, on the whole very accurately collated, make the Medical Register a very important publication. In this very Table there is given for the first time a complete statement of the number of persons whose names were entered in, added to, or removed from the Medical Register for each year from 1876 to 1884 inclusive. In the case of removals, the section of the Act under which the removal was made is given, and is ordinarily, of course, the 14th section, or that which empowers the Council to remove a name if, after a certain time, communications from the Registrar are unanswered. What strikes one as least satisfactory in this process is the irregularity with which it is done. In some years hundreds are removed, and in others only scores or less. Time and the experience of individual members of the profession alone will show how far the actual work of individual registration is done with accuracy, but there is little reason to doubt that ever-increasing pains are taken to make this volume what it ought to be.

THE interesting paper on the Diet of the Febrile State read at the annual meeting of the Medical Society of London by Dr. ALLCHIN, and which appeared in THE LANCET on the 7th inst., will no doubt give a stimulus to researches of a similar kind with regard to the dietetic treatment of disease generally. To this subject the ancients paid more attention than modern physicians have hitherto seemed inclined to bestow; for though we have many valuable treatises relating to diet, they mostly refer to the chemical constitution of the food stuffs and their digestibility, whilst little is said in reference to the modifications required to meet the altered conditions that arise in various pathological states. Indeed, very little is known respecting the tissue changes that occur in disease. It was only quite recently that the views originally enunciated by LIEBIG ceased to dominate our speculations with regard to the chemico-pathological processes occurring in fever. According to this view, it was held that the tissue changes depended on the amount of oxygen taken in by the lungs, so that on increased respiration a more intense combustion took place, metabolism was increased, with the production of more carbonic acid and urea. The natural outcome of this view was to support the idea that fevers required feeding; that more fuel was requisite to supply the loss due to increased combustion. The fact, however, that the increased excretion of urea usually precedes the rise of temperature, has strengthened the

supposition, which for some time has been gaining ground, that instead of increased metabolism being the result of increased oxidation, it is the increase of the intra-molecular action in the cells themselves that occasions the demand for oxygen. According to this view, the cells are supposed to be to a certain extent independent of the amount of oxygen supplied to them by respiration — that is, that though they originally obtain their oxygen by that process, they are able to store up a portion of it either for reserve or independent use. In fever, therefore, probably under the stimulus of the zymotic poison, the intra-molecular activity of the cells increases, their store of oxygen becomes exhausted, and the demand for a fresh supply leads to an increased frequency of pulse and respiration.

Now, if this view is correct, the propriety of giving an excess of food, especially nitrogenous—which is known to stimulate the intra-molecular activity of the cells throughout the body,—may be questioned. Then, again, with regard to the economy of oxygen which this theory entails, it is important to select a food which is itself easily oxidisable—that is, readily converted into carbonic acid and water. Speaking roughly, we may say that in the starchy and saccharine constituents of our food the carbon and oxygen are in equal proportions, whilst in the proteids the carbon is as three to one, and in the oleaginous constituents as eight to one. We know, however, so little of the synthetical and analytical processes taking place in the conversion of food into tissue that we cannot yet apply this knowledge to any practical deduction. If, as is now generally supposed, a considerable proportion of the starchy and saccharine matter is converted into fat, then during this synthetical conversion a large amount of oxygen will be liberated, which for a time is available for the requirements of the body. This would point very strongly to the conclusion that starchy and saccharine matters should form the basis of the dietary of the febrile state, though of course a certain amount of nitrogenous food is also required. It is not, however, sufficient merely to consider the question in relation to tissue metamorphosis, but the state of the secretions necessary for efficient digestion. These, as we know, are both qualitatively and quantitatively affected, and their activity diminished; consequently, if we would avoid fermentative changes resulting from delayed intestinal digestion, we must supply their place or add to their power by means of already partially digested foods. Unfortunately, however, the preparations hitherto proposed for this purpose do not combine palatableness with efficiency; an improvement in the former condition is therefore much to be desired.

It is not merely with regard to the dietetics of the febrile state that physicians are concerned; there are other diseases in the treatment of which diet plays a prominent part. Thus, in albuminuria Dr. AUFRECHT insists on the abstention from milk in nephritis, and others advocate treatment based upon the administration of skim milk solely. Who is right? Or if the question lies between the treatment of acute nephritis and chronic nephritis, at what period should the milk treatment be commenced? Then, again, there are questions with regard to diabetes that still call for solution, as for instance the advisability of enforcing absolute restriction from starchy food in protracted cases of the disease; some authorities maintaining that a too exclusive diet is in the long run more injurious than limited indulgence, whilst others maintain the reverse. Then as to the dietetic treatment of gout; we are here confronted with opposed opinions and diverse theories, and are puzzled to decide between the ascetics and those who advocate a more liberal dietary, or else to halt halfway with the disciples of SYDENHAM, who, whilst advocating temperance both in food and in drink, point to the danger of too great abstinence, and who think that whilst wine is injurious as an ordinary beverage more danger arises from the exclusive use of water. In scurvy and its allied disorders there are many questions still remaining for settlement, such, for example, as whether vegetables when preserved retain their antiscorbutic virtues. What is the exact position of fresh meat and milk as antiscorbutics? And, above all, what gives to a minute dose of lemon-juice such an enormous protective or curative power? Then, again, with regard to disorders of digestion, Dr. LAUDER BRUNTON, in the Lettsomian Lectures of this year, upset many of our well-established notions as regards their dietetic treatment. Those lectures and the present communication of Dr. ALLCHIN will mark an epoch in the history of dietetics, since at last it seems that the advanced physiology of the day is to be applied to the exploration of this hitherto neglected branch of medical practice. We hope, however, now the ground has been broken, that conclusions will not in future be so entirely based on theoretical and physiological statements, but that practical observations giving the results obtained with different diets under similar conditions will be placed on record.

THE scheme of Admiral Sir EDWARD INGLEFIELD, proposed and submitted for public adoption by the Prince of WALES, will be cordially accepted and supported by the medical profession. It is most fitting that the memorial to General GORDON should take the form of a hospital so placed as to satisfy a most pressing need for the advantage of all nations. His Royal Highness simply and eloquently expressed the sentiment of all classes of this and other communities when he said, "I think there is no institution which would have been more acceptable to General GORDON than a hospital with which his name would have been associated. He was, perhaps, one of the most unselfish of men ever known, and his thoughts were always of others." The great lesson of GORDON'S life was sacrifice; and the moral of his most lamentable death in the Soudan, through the procrastination of Ministers at home, was sacrifice in its last development. He lived for others and he died for others. It is a poor thing for this nation to commemorate his memory at all, seeing that it was by our neglect he was left to perish; but it is at least fit and proper that the form our memorial takes should be one in harmony with the character of the departed hero, whose death we "too late" mourn.

The Egyptian hospital at Port Said has long been a reproach to the age, not less than to the unhappy country whose degenerate state it too well indicated. Everything in Egypt, or under the blighting influence of the benighted government of a succession of incompetent Khedives, is contemptible; not merely for its intrinsic worthlessness, but for the mould of

decay that neglect and corruption encourage to grow over it. Some day, when the truth is no longer suppressed, and those who know Egypt and its rulers personally can speak out, the public conscience will be scandalised by a sense of the folly and weakness displayed in supporting the craven tyranny of selfishness and immorality under which the land of the PHARAOHS has so long languished. As a matter of fact, the rude people of the Soudan who are dying bravely at the points of our bayonets for their liberties and their homes are as much the superiors of the Egyptians in every attribute of manhood as the noble races of India are above the lower orders of "whites." England, as the greatest Mahommedan Power, had no more reason to range herself on the side of the Egyptians against the Soudanese than she would have in taking the part of the Muscovites against either of the lesser nationalities they have sought to oppress. The Mahdi, as a false prophet, might have been exposed and defeated in the name of ISLAM without butchering the Soudanese, whom he has seduced and enslaved mainly, if not entirely, because we have played fast-and-loose with the bankrupt puppets of Alexandria and Cairo. It is a miserable business, this Egyptian *fiasco*, look at it how we may.

A gleam of sunshine in the midst of the gloom falls on the grave of GORDON, who went out almost single-handed to try to repair the breach and to remedy the blunder his knowledge of both Egyptians and the Soudanese enabled him only too clearly to perceive. It will hereafter be a ray of comfort as we look back to remember that out of the muddle we have made one act of humanity in sympathy with the life-long ideal of the man so sadly lost to us has been performed by us, though it be after his death. The moral effect of a good hospital, constituted on cosmopolitan principles and properly administered, at Port Said, can scarcely fail to be considerable. It will be well if we are permitted to leave this one trace of benevolence in the region where we have left so many memorials which posterity will view with less complacency. We heartily wish the scheme success, and cordially endorse the claim addressed to all classes of the people for its support.

A CASE is now under the consideration of the Local Government Board which, it may be hoped, both on personal and on public grounds, will be dealt with in that spirit of generosity which the circumstances call for as a right. One of the Orders of that Board recites that every principal officer appointed to the fever and small-pox hospitals of the Metropolitan Asylums Board shall continue to hold his office until, amongst other conditions, he shall die, or resign, or be dismissed by the Board of Management with the assent of the Local Government Board, or by the Local Government Board, or until the Board shall consider it desirable that his duties should cease or should be modified. It is well known that since the report of the Fever and Small-pox Hospitals Commission a change of practice has been inaugurated by the Asylums Board as regards the future use to which the small-pox hospitals are to be put; and this change apparently renders it unnecessary, in the eyes of the Asylums Board, that there should any longer be two separate principal medical officers at each hospital. Hitherto one has had charge of the fever hospital, another of the small-pox hospital; but the rapid removal of small-pox patients to the hospital ships does away with all but a few beds for small-pox cases at each hospital centre, and the several isolation centres are now to be regarded essentially as fever hospitals only. At the South-Western Hospital at Stockwell Dr. F. R. BERNARD has had charge of the small-pox establishment; and the fact that he has remained in the service of the Board for nearly nine years, coupled with the circumstance that his salary was raised so recently as last year, and that he was selected for the extremely onerous duty of supervising much of the work carried on at the Darenth Camp, make it quite unnecessary to refer to the efficiency of the services he has rendered as an official of the Board and as a public servant.

But some two months ago he received from the Asylums Board an intimation that, since the two hospitals at Stockwell are henceforth to be under one medical head, application was about to be made to the Local Government Board to issue the order necessary to the dispensing with his services in the future. At first sight the despatch of such a letter to such an officer, under such circumstances, appears well-nigh incredible, but it would perhaps be wrong to infer from its official baldness that the letter of the managers implies that no proper recognition of the services which Dr. BERNARD has rendered will be made. The right of the managers to remunerate their officers is, at least nominally, limited by the need for sanction from the central authority; and it may be that, should that authority decide in favour of the views of the managers as to the appointment of one principal medical officer only at Stockwell, then the question of compensation for abolition of office will be subsequently considered. It is quite true that such compensation cannot be claimed as a right, but when a medical man has given the best and most energetic years of his life to public services of a specially trying character, and when his post is abolished as a mere matter of administrative convenience, the circumstances are such as, even on public grounds alone, to call for the exercise of liberality. Dr. BERNARD has been informed by the Local Government Board of the request which has been addressed to them by the managers, and he has been asked if he has any observations to address to that Board before they form a decision on the application. The observations which this last letter has called forth are naturally addressed to the subject of pension or compensation; and seeing that Dr. BERNARD will, if the order dispensing with his services should be issued, have practically to recommence his professional career, it is sincerely to be hoped that the central authority will make any abolition of his office contingent upon ample compensation in some form or other. Hitherto the Metropolitan Asylums Board have been able to command high-class services from men who have been ready to devote the prime of their lives to duties the performance of which has deprived those holding office of nearly all that social intercourse which is so highly valued by men who have had a scientific and professional training. Should the managers wish to retain their power of attracting to their service medical men of a similar standing they will do well, in such a case as Dr. BERNARD'S, themselves to initiate the proposal to offer adequate compensation on abolition of office. The proper stage in the official programme may not yet have been reached for the

embodiment of this proposal, but many will look for its advent, and all who are interested in the efficient medical working of the important hospitals which are placed under the management of the Asylums Board will hope that Dr. BERNARD'S retirement may be accompanied by conditions which will do honour to those whom he has so long and so faithfully served.

Annotations.

"Ne quid nimis."

PHYSIOLOGY AT CAMBRIDGE.

A DISCUSSION took place on Thursday, the 12th inst., in the Arts Schools at Cambridge, respecting a proposal to enlarge the physiological laboratory, and provide additional lecture and teaching rooms for physiology and pathology, at an estimated cost of £9000. The proposal is made in consequence of an urgent representation by Professor Foster of the necessity of such addition, owing to the rapid increase in the number of the medical students. It was, on the whole, favourably received. The Senate of the University of Cambridge have always regarded in a liberal spirit the study of physiology and the various subjects more or less directly connected with medicine, and have never yielded to the vivisection scare. Indeed, remarkable as it may seem to those who have followed the recent controversy at the sister University, and noted the excitement attended on it, the matter of vivisection was not even alluded to by any one of the speakers. They recognise it as a necessity to the advance of a science which is closely related to the welfare of the human family, and I take the common-sense view that certain evils must be incurred for the purpose of attaining great and good ends, and they trust to those whom they have placed in positions of responsibility, and with whom they are in daily personal intercourse, that the evils will be minimised as much as possible. The desirability, indeed the importance, of assenting to the request of the physiologists was not questioned. Even the financial difficulty was not unduly pressed, when we bear in mind the great and increasing demands upon the University chest—demands which far exceed the income, and which can be met only by borrowing, and so forestalling future revenue. This, it seems, will have to be done; and a careful statement respecting the funds of the University, and the disposal of them, lately issued by an eminent member of the Senate, with an estimate of prospective income and expenditure, shows that the current resources do not, and will not, more than meet the current needs, that there is no reserve fund, and that the extraordinary demands for building, &c., which necessarily arise must be provided for in some special manner.

DEATH OF PROFESSOR VON FRERICHS.

A TELEGRAM from Berlin on Saturday last conveyed the news that Professor von Frerichs was dead. Just twelve months ago the University was celebrating the twenty-fifth year of his professoriate, and many of his former pupils assembled to do him honour; for he was rightly regarded as the foremost exponent of clinical medicine in Germany. By awarding him the patent of nobility, the German Government showed that it recognised his high merit. Professor von Frerichs was born at Aurich in 1819, and studied at Göttingen, whither he returned after a brief period of practice in his native town, to serve as a *privat docent*. In his earlier years he showed by his work an inclination rather towards chemistry and physiology than to medicine; but in 1849 he commenced at Kiel the path of clinical medicine, which he further pursued at Breslau, where he went in 1851. At Breslau he was not only clinical professor, but also pathologist, and his pathological demonstrations were thorough and exact. Whilst there he published the first volume of his work on the liver, known to English readers in Murchison's translation for the New Sydenham Society. Besides this treatise on diseases of the liver, he wrote one on Bright's disease, in which he enunciated the idea that uræmia was due to poisoning by carbonate of ammonia; and last year he published a monograph on diabetes. Called to Berlin University in 1859, the reputation already gained adhered to him, and his clinic was attended by students from all parts of the world. Amongst his pupils were Naunyn, Quincke, Ewald, Eichorst, Litten, and Ehrlich. Professor von Frerichs had been president at the annual meetings of the German Medical Congress, which assembled last year in Berlin to do him honour. Next month the Congress reverts to its previous meeting-place at Wiesbaden, but its proceedings will be saddened by the loss which not the Congress only but the whole of Germany has sustained in his sudden removal. It may be well to recall the incident that happened last year to which we then alluded (THE LANCET, March 15th, 1884, p. 486) when he addressed his class at the close of the fiftieth session of his labours at the university. He said "it was with mingled feelings of joy and sorrow that he concluded the course. Thousands had sat on those benches, and were now scattered not only throughout Germany, but in all parts of the civilised world. It had been his aim to instruct them in the methods of examination of patients, how to weigh the signs of disease and form a diagnosis, and they had frequently been able to see the confirmation of the latter in the post-mortem room. And he had tried to show how treatment on physiological grounds was related to diagnosis. The material was inexhaustible, and could he lecture for another twenty-five years it would still be unexhausted, so true were the words of their old master Hippocrates, that 'life is short, and art long.'"

THE BRISTOL COMMISSION ON THE POOR.

THE town of Bristol has organised its own committee on the housing of the poor, and it may be congratulated on having accomplished its mission with a thoroughness and promptitude that are not unworthy of serving as an example to the larger body investigating the same subject in London. The result of the inquiry, published in a compact volume, may be studied with advantage, as most of the questions put and answered apply equally well to almost every centre of population. Indeed, they apply with perhaps greater force to other towns than to Bristol, which in 1883 was able to show a lower death-rate than any of the twenty-eight large towns of England. The general death-rate of Bristol in that year was only 17·9 per 1000, and the zymotic death-rate 1 per 1000. Yet in 1850 the death-rate was 28 per 1000; but since then the town has been thoroughly drained, cellar dwellings abolished, and considerable improvement made in the condition of inhabited houses. The good work is not, however, yet complete. There are many houses still which have no back yards, no back windows, and no through ventilation. In several of these houses a man, wife, and adult children were found living in a single room; yet the rents, though too high, are much lower than in poor quarters of London. To this promiscuity of the sexes is attributed much of the prevailing immorality, other causes of which are also pointed out by the commission. "The harshness of parents and the hardness of all classes of society" towards young women after their "first fall" are, according to the report, the principal causes that drive young girls to prostitution, and the commissioners urge that more charity

be exhibited to the erring, believing that "if more mercy were shown by parents, friends, and the public after a first fault, many lives would be saved from ruin." The absence of such truly Christian charity has brought about the most deplorable results, and medical evidence goes to show that syphilis of a virulent type prevails extensively among the loose women of Bristol, whose ages vary from twenty to thirty, though younger girls seem comparatively exempt. The action of the School Board is much praised in having rescued young children from immoral and unwholesome surroundings. As remedies, the commissioners recommend a more strict application of the Sanitary Act, the purchase of likely property by committees or societies who will befriend their tenants, content themselves with reasonable profits, and watch over the sanitary condition of the houses they sublet. The poor require "personal service" more than almsgiving. "The relations of landlord and tenant should beget a worthy sense of kinship," and the call for rent be looked upon as the weekly visit of a sympathising friend. But this ideal state cannot be expected where poor tenements are farmed out to money-making speculators. The report testifies to much arduous work; and though it bears the impress of certain narrow class prejudices, such as the dislike of political clubs for working-men, the citizens of Bristol have, in this endeavour to better the condition of the poor, set a good example.

THE PATENT MEDICINES STAMP TAX.

LAST week the Chancellor of the Exchequer, in the House of Commons, in reply to Dr. Cameron's question on the Patent Medicines Stamp Tax, stated that he had been in communication with the Board of Inland Revenue, and had also consulted with the President of the Council. A Bill or Bills would be introduced, but it was impossible to say what steps, if any, would be taken during the present session. This vague answer has, we understand, given general dissatisfaction, and the *Western Morning News* and other influential provincial papers state emphatically that "the whole thing from a revenue point of view is despicable." It is pointed out that ample time has been afforded for a careful consideration of the subject in all its bearings, and that the public have a right to expect some more definite declaration of policy on a subject which affects so vitally the well-being of the nation. On Monday night the question again occupied the attention of the House, and Mr. Puleston asked the Chancellor of the Exchequer whether his attention had been called to the following statement which had appeared in a leading article in THE LANCET—viz., "Scarcely a day passes without the record in the papers of an inquest on some poor deluded victim who has been sent to his last account from an overweening confidence in one or other of the much-belauded patent medicines. The facility afforded for obtaining narcotics, whether it be in the form of opium, morphia, or the deadly chloral, is a consideration which cannot be overlooked. In no other country can poisons be purchased wholesale without a strict inquiry as to the purpose for which they are required, but in England they are sold openly and without restriction under the guise of patent medicines." And whether having reference to the proposed legislation on this subject, he would cause inquiry to be made, with a view to obviating the evils arising from such a condition of things, if they were shown to be as stated. To this the Chancellor of the Exchequer replied that, considering the very large number of articles on the subject which had appeared in all the papers, both medical and general, it was quite out of his power to give an opinion on any particular observation contained in them. He had already stated that the matter was under consideration, and that legislation would be proposed either in this or next session. This answer, we must confess, seems to us to be even more unsatisfactory than that given in reply to Dr. Cameron's question. Mr. Childers seems to be strangely oblivious to the fact that more than six months ago he undertook publicly to obtain certain documents and study them "with care."

THE LATE GENERAL STEWART.

THE Editor of the *Manchester Courier* has courteously favoured us with a report of General Stewart's wound, just received from their correspondent in the Soudan. From this we learn that the gallant General was struck by a bullet over the left anterior superior spinous process of the ilium, and that the ball passed along the iliacus muscle, produced a stellate fracture of the posterior part of the ilium, and lodged in the upper end of the left sacro-iliac synchondrosis. The peritoneum was not wounded. Death was caused by exhaustion on Feb. 16th, between Abu Klea and Gakdul. Assuming that this is a complete description of the injury, it is evident that the wound was not necessarily fatal, although a very grave one, in which extraction of the bullet was not practicable. As we had occasion to remark in connexion with the wound of the late General Garfield, the mere lodgment of a bullet in the tissues of the body is not necessarily a fatal or grave lesion. In such a case as General Stewart's everything depended upon whether it were possible to render and to keep the wound aseptic. If the bullet carried in germ-laden foreign bodies, portions of clothing, &c., and these could neither be removed nor properly cleansed, septic suppuration would be set up, with all the dangers of systemic poisoning, exhaustion from the constant drain, or spread of the inflammation to the neighbouring serous membrane. This appears to have been the case with General Stewart, and the fatal result was probably due in greater part to a form of septic absorption than to the mere drain upon the system entailed by the continuous secretion of pus. This view receives considerable support from the fact that there was marked fever during the last few days of the General's life.

THE PROTECTION OF ABANDONED CHILDREN IN FRANCE.

WE recently noticed the efforts made by the French Legislature to protect the health of infants, and gave some description of the results attained by the application of the "Roussel Law." A few words as to what voluntary effort is doing for children who have emerged from the period of infancy may not be out of place. The Parisian General Society for the Protection of Abandoned or Criminal Children was founded by M. Georges Bonjean some five years ago, and in 1880 the subscriptions given for this work did not exceed £152; but the next year the amount collected reached the respectable figure of £2240. In 1882 there was a further increase, for the subscriptions are set down at £5080. In the following year £5880 were given, and £6840 in 1884. The number of members of the Society increased from 2040 in June, 1881, to 12,648 in the present year. The work done by the Society is in due ratio to the support it has received. In February, 1883, it gave assistance and education to 700 helpless children; while at the present moment no less than 2828 children are under its protection. All these children are carefully drilled; and, while every effort is made to give them the education necessary to enable them to earn an honest livelihood, special care is taken that they should have the food and exercise necessary for the preservation of health and the development of physical strength. This work, however, though good, is not sufficiently extensive. It is not two or three thousand children, but something like a hundred thousand, who need such protection. Nevertheless, the Parisians are to be congratulated

on taking the initiative in this matter, instead of relying solely on the State. The French charities are not to be compared in importance and extent with those of England. Till recently the form of government did not tend to develop self-reliance, and the lack of this quality is accountable for many evils. Little sanitary improvement would have been accomplished in England if pressure had not been brought to bear upon abuses by private individuals; and, to progress, the French must take such questions into their own hands without waiting for the Government to set the example.

ARMY RECRUITING IN 1884.

THE annual report of the Inspector-General of Recruiting has been presented to Parliament earlier than usual, and in consequence does not contain many of the tables relating to the physical condition of the recruits. These will shortly be issued in the Annual General Return. In the meantime, we may note that in 1884 the large number of 64,853 recruits were medically examined, of whom 27,807 were rejected, being in the ratio of 429 per 1000; but this includes a number, not stated, rejected as under height, which is clearly a military, not a medical cause. The standard of minimum age was eighteen; height, 5 ft. 4 in.; chest measurement, 33 in.; weight, 115 lb. "The chest measurement and weight according to height is left to the discretion of the medical officer, who is governed by the appearance of the man, by his physical condition, and his power and prospect of development." Of the 35,653 who joined the service 12,896 volunteered from the militia. General Bulwer states, as the result of personal visits to several of the recruiting districts, that, in his opinion, the quality of the recruits compared with that of former years is "by no means unfavourable to the men of the present day;" and this opinion appears to be in accordance with that of the officers commanding regimental districts and auxiliary artillery districts, with a very few exceptions; it is also to some extent borne out by the fact that in 1884 the proportion of men invalided during their first year of service was 9·7 per 1000, while the average of the preceding four years was 12·0 per 1000. In addition to the recruits raised for the army, there were 36,067 enlisted into the militia, but we are not informed how many presented themselves for enlistment and were rejected. As we have already seen, the number transferred from the militia to the general service was equal to one-third of those passed into the militia. When the returns are published, we shall probably be able to extract from them additional interesting information respecting the physique of the men who are being added to the strength of the army.

SEWER MEN AND TYPHOID.

DURING the reading of the report of the medical officer, Mr. M. A. Adams, to the Maidstone Local Board, some questions were asked about a man who died of typhoid fever who had been employed in repairing a sewer. Mr. Adams said that the man had told him that he was more subjected to the effluvia than the bricklayer to whom he had to hand the bricks. He added that some one must do this sort of work, and he did not think any blame attached to any one. One of the members of the board stated that "at the last outbreak of cholera in London the Board of Works furnished their sewer men with some kind of drink, and it was remarkable that although these men were working constantly amongst obnoxious smells, none of them were attacked with cholera." He then moved a resolution requesting the medical officer to suggest to the surveyor some drink or other preventive which would render the sewer men less liable to infectious disease. Mr. Adams said it was a difficult thing to be asked. People fancied that he himself had something in his pocket which prevented him from contracting small-pox &c. He, however, had nothing of the kind any more than any member of the board. If he knew of anything which would be of service to the sewer men, he would make use of it at once. The days when doctors carried a gold-headed cane containing fragrant essences for antiseptic purposes are past, and it would be well for members of local boards and others to understand that disease germs such as are contained in typhoid stools ought to be disinfected before they reach the sewer, which should itself be subjected to the action of similar agents, and, above all, thoroughly well ventilated through properly constructed shafts. There would then be less faith in prophylactic draughts, camphor lockets, and other charms for the prevention of infection.

OVERTIME IN GOVERNMENT ESTABLISHMENTS.

THE Factory Acts being liable to suspension in Government establishments, the men and boys in Woolwich Arsenal have of late been working overtime, the men working from 6 A.M. to 9 or 10 P.M., many of them Saturday afternoons and Sundays; the boys from 6 A.M. to 8 P.M., but not Saturday afternoons or Sundays. It is doubtless more convenient to the authorities to make the same persons work long hours than to engage additional hands, who must necessarily be more or less new to the work and who would require more looking after. But such protracted labour tells heavily on the health, and it is known to neighbouring practitioners, and doubtless to the arsenal medical officers also, that some are breaking down under the strain. The hours of labour permitted by the Factory Acts ought to be respected, in spirit at least, even in Government establishments in times of extra pressure. It seems most anomalous that in such an establishment as Woolwich Arsenal a boy may be compelled to work for such a number of hours that his health may become permanently impaired while a private manufacturer who ventured to treat him i the same way, no matter under what emergency, would be heavily fined. We understand that no work was done last Sunday, and that the excessive overtime has been diminished during the present week by order of Colonel Barlow.

THE METAPHYSICS OF NATURAL HISTORY.

A DEMONSTRATION of the alliance between religion and science, though to some it may appear to be difficult or hopeless, is, as we have already had occasion to remark, by no means impossible, however the terms of its exposition may vary with our fluctuating knowledge. We have here two doctrines, each professing to explain the cause or causes, the working, the objects, and the whole meaning of things as they exist around us, and of our own being, and each having for its more or less direct intention the education and improvement of that being. The one offers to us, as it were, by a mystic conception a statement of the living sense, the spirit or essence of that which we call Nature—namely, that good and God are in it, and therefore it exists and prospers; that failure, decay, and physical and moral bankruptcy come about by the introduction of some flaw, some force or Power of evil. The other, limiting its view chiefly to material objects and the methods of their actions, founds its maxims upon ascertained laws and their effects, but still it teaches the same essential facts; and while it may leave out as unproved the character of their primal cause, it cannot ignore this, nor deny that all its subject matter shows the efforts of design. It is in the consideration of such design and all that it implies that natural history as a study reaches its highest philosophical point, and even acquires a moral function above that of intellectual training, in its revelation of the mind and character of a divine Being. It has always appeared

to us that science, by revealing many proofs of adaptation in animal and vegetable life, has fortified, instead of undermining, the structure of religious belief. Where there is adaptation there must have been these necessary antecedents, a reason for it, and a mind to perceive and conform to that reason. It is incredible that the many and varied forms of matter with which we are familiar should have been the outcome of a mere chance jostling among the elements of chaos. Matter may be moulded by circumstances in obedience to some method, but there is nothing to show us that method is itself an inherent property of matter. It would rather seem, as has been ably stated in a pamphlet recently published by Dr. Stephen Monckton, that there is within all natural action an intelligent will-force which can and does interest itself in every atom concerned in the great changes of evolution, presiding over its creative origin and further history, and exercising a single and beneficent, though not a uniform, influence among the changing needs of organic and inorganic bodies, of the animalcule and of man, of health and disease, of historic races, and of the moral principles engrafted in human minds. According to Dr. Monckton, this influence must be incorporate with its subject material. He argues on this point not without reason, that such an all-directing will-force may have personal attributes, and be as fully in accord with the words of Scripture as is the idea of a personal but omnipresent God; while this presentation of an ancient belief must aid the scientific mind by affording, at least, an approximately satisfying definition of the Divine nature.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

AT the meeting of this Society next Tuesday there will be a discussion on Cholera, to be introduced by a paper from the President. Microscopical specimens and cultivations by Drs. Klein, Gibbes, Watson Cheyne, Heron, and Professor Warden will be on view, and the greater part of the evening will probably be occupied with etiology. There will, in all probability, be an adjournment of the debate to an extraordinary meeting on Tuesday, March 31st, when the pathological and therapeutical aspects of the subject will be more especially discussed. Amongst those expected to take part in the discussion are Sir H. Acland, Mr. Watson Cheyne, Dr. Chevers, Sir J. Fayrer, Dr. Gibbes, Dr. Heron, Sir Guyer Hunter, Mr. V. Horsley, Dr. Klein, Dr. Lewis, Mr. Macnamara, Dr. Geoffrey Marsh, Inspector-General Murray, Dr. Pye-Smith, and Professor Warden.

THE CONSTITUTIONAL TREATMENT OF UTERINE DISEASE.

THE paper read at the last meeting of the Medical Society brought together the alleged conflicting elements of neurology and gynæcology. The impression seems to have got abroad that Dr. C. Allbutt in his Gulstonian Lectures had denounced the physical examination of women as well as the local treatment of uterine disorders. We were not aware, and we were confirmed in our impression by the speech of Dr. Allbutt last Monday, that he had done anything of the kind. It is true that Dr. Allbutt considered that some cases of disease in which the uterus was also involved were treated on an entirely wrong plan, and to this point he still adheres. We must acknowledge that the position taken up in the Gulstonian Lectures last year seemed to us to be most logical, and may be briefly put thus: The uterus may be diseased primarily, and may then cause disease of the nervous system; the nervous system may be affected in the first place, and the uterus involved secondarily; the uterus may be diseased alone without giving rise to any nervous symptoms; the nervous system may be involved without causing uterine disorder.

LYING-IN HOSPITAL MORTALITY.

THE mortality of lying-in hospitals used to be a matter of just reproach. It promises to become so low as to excite the emulation of private practitioners. The report of the General Lying-in Hospital of York-road, Lambeth, for the year 1884 is before us, and calls for our hearty congratulations to the committee, and especially to the medical staff. The charity not only provides for the in-door accommodation in confinement of married women, but has an out-door branch of work; and under both heads the results are very remarkable. There were of in-patients 334, of whom only one died; and of out-patients 741, of whom none died. The medical report is modestly short. We could have wished for more information as to the methods by which such good results have been obtained. We may surmise, from Sir Joseph Lister's name as that of the consulting surgeon of the hospital, that antisepticism is the secret of the success. This explanation is confirmed by the Book of Rules of Nursing, to which reference is made in the report of the medical officers of the hospital, Dr. John Williams and Dr. F. H. Champneys, in which antiseptic injections figure largely. According to this manual every lying-in patient is douched night and morning, until the lochia have ceased for two days in succession, with an antiseptic solution of perchloride of mercury (1 in 2000 parts) at a temperature of 110°. Besides this measure, every precaution is taken, by ventilation and otherwise, to preserve the sweetness of the atmosphere, and the purity of hands, instruments, bedding, &c. The hospital is further useful as a training school for nurses, and in this capacity is in demand by an increasing number of candidates year by year. The institution seems in every way well worthy of support.

THE CAMDEN TOWN TRAGEDY.

AN inquest was held by Dr. Danford Thomas at Crowndale Hall, Crowndale-road, on March 11th, respecting the death of Charles Wheaton, who was alleged to have been shot by a fellow-lodger named John Rose. It transpired that the deceased and the supposed murderer were scarcely known to each other, and no motive could be found for the commission of the crime. We understand the prisoner has more than once been confined in a lunatic asylum, but as the case is *sub judice* we forbear commenting on its merits. From the evidence it seems that Wheaton was attacked whilst in bed, and that having received several revolver shots he rushed into the street. On his admission to the London Temperance Hospital it was found that he had four wounds, apparently produced by bullets, one each on the head, the face, the chest, and abdomen. It was surmised at first that the shot which struck the tenth left costal cartilage had travelled along the rib to the side of the spine, where it was found and extracted; but later, when symptoms of peritonitis supervened, it became apparent that the abdominal cavity had been penetrated. Two other bullets were removed during life, one from behind the left ear and the other from the sternum. The patient died on the third day. At the post-mortem examination it was found that the bullet which produced No. 1 wound struck the skull two inches and a half behind and half an inch above the upper attachment of the left ear, immediately over the lower part of the parieto-occipital suture. It had then passed forwards for about an inch. The hair was singed. The bone was not fractured, but a subjacent convolution of the brain was bruised. No. 2 wound consisted of a trench passing obliquely downwards and forwards on the left side of the face, the groove deepening from above downwards. The upper extremity of the wound was situate one inch and three-quarters in front and one inch below the external auditory meatus, and the adjacent portion of skin was peppered with large grains of powder. In a line

with the foregoing, and clearly made by the same missile, was No. 3 wound, over the middle of the sternum on a level with the lower border of the first costal cartilage. It passed downwards, backwards, and to the right, and ended opposite the first intercostal space, the sternum at this spot being slightly ploughed up. There were no powder marks around. No. 4 wound, the fatal one, was on the left side of the abdomen. The tenth costal cartilage was shattered. The omentum and jejunum were perforated, and the bullet having traversed the psoas muscle had passed backwards between the transverse processes of the second and third lumbar vertebræ and became arrested beneath the skin. There was general peritonitis, but the inflammation was most marked along the track of the bullet. Apertures corresponding in position with the orifice of the wound in the abdomen were found in the two shirts worn by the deceased man at the time of the affray; that in the outer shirt was surrounded by a blackened zone some two inches in depth, whilst the one in the inner was marked by a much narrower and fainter ring. No. 5 wound consisted merely of a furrow on the outer side of the left little finger, where the soft tissues had been torn up and stained by the bullet. With the exception of the last, all the wounds were evidently caused by a revolver fired close to the body; and the first two, though it was possible they might have been self-inflicted, could only have been so with the hand in an unusually strained position. For the wound behind the left ear to have been self-inflicted the shot must have been fired with the left hand. The haemorrhage and signs of inflammation about all the wounds showed the latter were received during life. The jury returned a verdict of death from peritonitis following a penetrating wound of the intestine, and held the prisoner chargeable with having caused the death of the deceased. Subsequently the prisoner was committed by the magistrate at the Clerkenwell Police-court to take his trial for murder at the next sessions of the Central Criminal Court.

THE PHYSIOLOGICAL ACTION OF HYOSCINE.

DR. H. C. WOOD of Philadelphia has recently published in the *Therapeutic Gazette* a series of observations on the physiological action of hyoscine. It has long been known from the researches of Ladenburg and others that henbane contains two active principles, amorphous hyoscyamine—which is quite distinct from true or crystalline hyoscyamine and hyoscine, an alkaloid yielding crystallisable salts. Dr. Wood in his observations has employed the hydrobromate almost exclusively, but in a few cases he resorted to the hydriodate. He finds that frogs are sensibly affected by $\frac{1}{65}$ of their weight of hyoscine, but that at least $\frac{1}{500}$ is necessary to produce a toxic action. The symptoms are very uniform. They consist of an increasing sluggishness, with a progressive loss of voluntary movement and a corresponding depression of the reflex activity, but without marked loss of sensibility. Death is brought about by failure of breathing, the heart beating for a considerable time after arrest of respiration. From this it would appear that in the case of the frog hyoscine acts as a motor-spinal depressant, killing by arresting respiration probably through a central influence. Any action that may be exerted upon the circulation is of a depressant character, but is so slight as to be of no importance. From a number of observations made on mice, cats, and other animals, it is seen that hyoscine acts upon mammals "chiefly as a spinal depressant; that it is a centric respiratory depressant, causing death by asphyxia; that it has very little effect on the circulation, what influence it exerts being in the normal animal set aside by the asphyxia it produces; that it does not paralyse the pneumogastrics; that in enormous doses it paralyses the vaso-motor system, and that on the heart itself its influence is very feebly depressant." Several experiments were made on the resident medical staff of the Philadelphia Hospital, and it was found that $\frac{1}{100}$ of a grain injected hypodermically always produced well-marked constitutional effects. The symptoms usually came on in about ten minutes, and consisted of dizziness, impairment of vision, dryness of the mouth, and an inability to walk straight. In some instances this was followed by deep sleep, lasting for many hours. Observations are being made on the clinical uses of hyoscine and it is anticipated that valuable results will be obtained especially in the treatment of certain forms of mania.

ALLEGED SUCCESSFUL TREATMENT OF HYDROPHOBIA.

A NATIVE surgeon, M. Nursimula, has written a letter to the editor of the *Times of India*, from which it would appear that he has treated successfully a case having all the symptoms of hydrophobia. The treatment adopted was the subcutaneous injection of a sixteenth of a grain of atropia. The breathing became infrequent (12 per minute), and the pulse slowed to the rate of 50 per minute. A quarter of a grain of morphia was injected hypodermically as an antidote to the atropia, and this was repeated several times. The symptoms disappeared the third day after the onset of the malady. The patient was a soldier, aged twenty-four, who had been bitten by a dog the week before the symptoms resembling hydrophobia appeared. If the case were one of hydrophobia, it must be allowed that the period of incubation was very short; the dog is not stated to have been mad, and it must not be forgotten that the presence of symptoms closely resembling, if not identical with, hydrophobia, do not *prove* that the case was one of genuine rabies.

FEES FOR NOTIFICATION OF INFECTIOUS DISEASES.

THE Health Committee of Birmingham have had under consideration the question of fees for the notification of cases of small-pox and scarlet fever, and have decided upon the following scale, to take effect after the 31st inst.:—"1. For the notification of cases where the patient is not removed to the borough hospital, 2*s.* 6*d.* 2. For the notification of cases where the patient is removed to the borough hospital, 5*s.* 3. For the notification of the existence of either of the diseases where more than one member of a household is affected at the same time, only a single fee will be paid, unless the patients are removed to the borough hospital; the fee of 5*s.* will be paid for each person so removed."

"DEATH AND THE DOCTOR."

OUR contemporary, the *Norwich Argus*, devotes a leader to the expression of its disapproval of the views of the coroner, Mr. Bignold, and of Dr. Doyle of Norwich, in reference to a case in which Dr. Doyle had been summoned out of his bed to testify to the death of a man who had expired in the night "plainly from apoplexy the result of an indigestible supper." We have not the full particulars of the case before us, so we write with some hesitation. But neither had the coroner, nor, for that matter, the *Argus*. We must say that the views of our contemporary on the respect due to the event of death (in which we entirely concur) would have been better enforced by descanting on the defects of the inquiry, rather than by reflecting on the doctor who left his bed to see the dead man and who was quite within his rights in complaining of the heartless want of public provision for the payment of medical men who do innumerable acts of humanity cheerfully and gratuitously in the dark hours of winter nights when their newspaper

critics are fast asleep. It is slight atonement for the *Argus's* strictures on Dr. Doyle that it devotes a line or two to the cheap praise of a noble and disinterested profession. The profession has been too much put off in this empty way. It will no doubt continue, as will Dr. Doyle, to act in the night as in the day. But that does not acquit the public and organs that should guide the public to a better recognition of their duties in regard to acts of mercy done in the night. We cannot conclude without a word on the unsatisfactory and inadequate inquiry into this case. The death of a human being unexpectedly in the night disposed of on the easy theory of an indigestible supper! This is disrespectful alike to life and to death. The theory has no basis, apart from a post-mortem examination, but it is flippantly adopted by our contemporary, who is in haste to devote a whole column of abuse to the doctor who left his bed to see the dead man.

OBSTETRICAL SOCIETY OF LONDON.

ON the 4th inst. Dr. Potter took the chair as President for the first time since his election, in succession to Dr. Gervis. There was a large attendance to hear the presidential address, which was listened to with marked approbation. After alluding to the wish of Dr. Gustavus Murray to postpone his candidature and not to hold office on this occasion, and also to the difficulty of following so judicious and so popular a president as Dr. Gervis, Dr. Potter reviewed the work of the Society and its objects, which he characterised as, first, political and social, and, secondly, scientific. He then gave suggestions for work in the future, and quoted Dr. West's introductory address of 1877 as to the position to be aimed at by obstetricians—"not that of mere specialists,..... but rather that of sound physicians and able surgeons, who for the public good have superadded to their general knowledge a particular acquaintance with certain departments of their art." He then expressed disapproval of the recent tendency to excessive local and surgical treatment of the diseases of women, to the exclusion of the constitutional aspect. The rest of the evening was occupied by the adjourned debate on extirpation of the uterus for cancer, arising from a paper by Dr. W. Duncan. The general sense of the whole debate seemed to be that for cancer of the cervix the operation is not justifiable, while for cancer of the body its justifiability is doubtful. We do not expect either operation to take root in England.

POISONING BY COLCHICUM.

A CASE of suspected poisoning by colchicum is just now attracting some attention in Paris. The accused is a person named Ribout, an artificial flower maker; and his wife having died suddenly, it was suspected that he had made away with her in order that he might marry his mistress. The remains of Madame Ribout were accordingly disinterred, and were submitted to a long and careful examination by M. L'Hôte, the chemical expert attached to the Paris Criminal Court. It is said that indications of the presence of colchicum were discovered, and that little doubt could be entertained that the unfortunate woman met her death from the administration of poison. It has long been known that meadow saffron is a powerful toxic agent. As far back as 1839 the case was recorded of a gentleman who took an ounce and a half of colchicum wine by mistake, and died in four hours. The symptoms are usually severe, and are fairly characteristic. At first there is burning pain in the stomach, with persistent vomiting and purging, the stools being mixed with blood. Irritation of the throat and intense thirst are soon added. The patient suffers from great prostration, pain in the head, a small weak or irregular quick pulse, muscular twitchings, and severe pains in the extremities and joints. In some instances the symptoms have been not unlike those of malignant cholera. At the post-mortem examination the stomach and intestines are usually found to be greatly inflamed, and purple patches are sometimes noticed on the skin and internal organs. A curious case of poisoning by "gout pills," composed chiefly of colchicum, was recorded in THE LANCET of March 15th, 1881.

"PROBABLY APOPLEXY."

AN inquest was held at Brookfoot on March 11th, touching the death of Elizabeth Beaumont, aged forty-seven. It appears from the evidence that the deceased had been somewhat excited on account of her daughter's marriage, and that she sat down in a chair in the pantry, and passed into a comatose condition, which her relatives mistook for natural sleep. She never recovered consciousness. The medical man summoned to deceased was not called at the inquest, but the coroner seems to have acted on the report of one of the witnesses, that in the opinion of the doctor death was due to apoplexy. We have it on the authority of Mr. G. A. Farrer that he expressed no such opinion. It is to be regretted that this gentleman was not asked to give his view of the case, for, to say the least, the death was not anticipated. The verdict of the jury was consistent with the facts deposed to at the inquest. Notwithstanding, we maintain that it is desirable in all cases where the cause of death is not manifest to take the evidence of a legally qualified practitioner. If the coroner is not a medical man, he cannot be expected to have the necessary knowledge to interpret the signs and symptoms indicating the mode of death described by ordinary witnesses.

MEDICAL HEROES.

AT a medical press dinner which took place at the end of last month in Madrid, there was present by special invitation Señor Fernandez Valdes, medical officer of the steamship *Gravina*, who was the means of saving the lives of 170 of the sailors of the Philippines. An official deed was also read setting forth the heroic and self-sacrificing services rendered to the sufferers during the terrible earthquake last Christmas-day by Dr. Miguel Hernandez Lozano, district medical officer of Pinos del Valle.

A HALFPENNY A WEEK.

THE Sheerness working men appear to be under the impression that satisfactory medical attendance, medicines, splints, &c., can be really obtained not only for themselves, but for their wives and children, for a halfpenny a week per head. An enthusiastic meeting has been held to promote a scheme for a "Medical Association" on the above terms. A statement was then made that the Portsmouth Association now contains 10,000 members, who actually pay their doctors —we wonder how many—between £300 and £400 per annum. If this is a fact, we can only express our astonishment that any medical man can be found to work on such unremunerative terms.

THE SPLEEN IN SYPHILIS.

THE view advocated by Mr. Jonathan Hutchinson that syphilis may be regarded as an acute specific fever in which the various stages are much more prolonged than in the ordinary acute specific fevers is one which cannot fail to keep the mind open to the possibility of the occurrence of those phenomena which are most usually associated with specific fevers. Facts dealing with the occurrence of alterations in the size of the spleen in syphilis are of course familiar to all, but the enlargement of the organ in the early stages of acquired syphilis still remains a debateable ques-

tion in the minds of some clinical observers. In a paper contributed to the *Vierteljahresschrift für Dermatologie und Syphilis* by Dr. Avanzini of Innsbrück, the author contends that the spleen undergoes demonstrable enlargement just prior to or in that stage of syphilis when the skin and mucous membrane are the seat of the ordinary secondary manifestations. He has also observed that after treatment diminution in size of the spleen sufficient to cause the disappearance of the cutaneous and lymphatic lesions does not take place.

A DEADLOCK IN LUNACY.

WE are very glad to find that workhouse authorities are declining to allow justices of the peace to any longer use those institutions as places of detention and remand for supposed or alleged lunatics. The deadlock created will hasten the search for a key to the difficulty.

THE total death-rate of Brooklyn for nineteen years (1848-1850 inclusive, and 1871-1876 inclusive, these being the only years of which the records are in a shape to be easily analysed) from all diseases was 116,910. Of these, 21,370 were cases of death from diseases of the nervous system. Deaths from accidents befalling the nervous centres, and deaths not directly due to nervous diseases, are not included in this total. The death-rate in the city of Brooklyn from nervous and mental disease may, therefore, fairly be said to be 19·43 per cent.

WE are informed that Her Majesty's Government has consented to distribute gratuitously to each registered member of the medical profession in the United Kingdom a copy of the revised edition of "The Nomenclature of Diseases," which has been prepared with much care and labour by the Royal College of Physicians. It is expected that the work will be in the hands of the profession within two months from the present time.

THE Committee of the Maidstone Local Board which manages the Infectious Diseases Hospital report that there are now three cases of small-pox. They advise an inspection of dustbins at the backs of cottages, and a report from the inspector of nuisances of the state of drainage of all the cottages. Alderman Spencer remarked on the advantage the hospital had proved to the town, and stated that its total cost during the last six months had been only £110.

La Gazeta Medica Catalana reports the case of a young primipara of feeble constitution, who, after the second month of pregnancy, was a great sufferer from vomiting. A variety of known remedies proved useless, when Dr. Mendez advised ether irrigation or spray on the epigastrium. The effect was instantaneous; vomiting at once ceased. It recurred twice during the pregnancy, but each time yielded readily to the local ether treatment.

WITH a view of being prepared for any emergency during the ensuing summer, the Port of London Sanitary Authority have decided to acquire an additional two acres and a half of land adjoining their Hospital for Infectious Diseases at Gravesend. Under any exceptional circumstances tents can be put up on the land. It is proposed to build a powerful steam launch for the conveyance of sick persons.

THE death is announced of Dr. Angel Villar, of Matías, Knight Grand Cross of the Order Isabel the Catholic, President of the Academy of Medicine and Surgery of Salamanca.

AMONGST the sick and wounded officers who have arrived at Cairo from the front are Staff-Surgeon Drew (suffering from hepatitis), Surgeon-Major W. H. Garde (suffering from dysentery), and Surgeon J. P. Myles (suffering from simple continued fever); they are all, however, reported to be doing well. The death of Surgeon Bradshaw at Korti on the 14th inst. from enteric fever is also announced. This is the second medical officer who has fallen a victim to that disease.

THE Vaccination Officers' Association has issued a first report, from which it would seem that the Association is in an active state, and doing good work in discussing questions affecting the working of the Vaccination Acts from the important standpoint of vaccination officers. Public vaccinators, medical officers of health, and others, are eligible as honorary members.

AT the meeting of the Metropolitan Board of Works on the 13th inst., recommendations of the Finance Committee that advances of £18,000 and £86,377 be made to the Metropolitan Asylums Board at the rate of 3½ per cent. were agreed to. The latter sum is to meet the expense of building the hospital at Winchmore-hill.

THE Rev. Henry Arnott, F.R.C.S., formerly Assistant-Surgeon and Lecturer on Pathology at St. Thomas's Hospital, has been appointed to the valuable rectory of Beckenham, in succession to the Rev. W. Cator, whose curate he formerly was. Mr. Arnott preached the sermon at Gloucester at the recent ordination.

CERTAIN new regulations for the examinations for the degree of Bachelor of Medicine of the University of Durham, to come into force on May 1st next, have been adopted, particulars of which will be given in our next issue.

WE are glad to learn from the *Boston Medical Journal* that the Index Medicus is to be continued "under the same conditions as heretofore," under the auspices of the publishing house of Parke, Davis, and Co.

THE Delegates of the Oxford Common University Fund have appointed Mr. Arthur Thomson, Senior Demonstrator of Anatomy in the University of Edinburgh, to a lectureship in Human Anatomy.

A PRIVATE letter dated Heidelberg, March 9th, is reported to contain an announcement of the serious illness of Von Bunsen, the distinguished chemist.

VOLUNTEER MEDICAL STAFF CORPS.—This corps is to be enrolled on April 1st. For the past year, however, the members of this corps have been drilling and acquainting themselves with the many duties devolving upon them. They are so far advanced, that it is believed the greater portion of the members of the corps will be pronounced efficient when enrolled. On Saturday, March 14th, the corps paraded, 300 strong, at Wellington Barracks, when it was inspected by Sir Guyer Hunter, K.C.M.G., in the presence of the Director-General of the Army Medical Department, Surgeon-General McKinnon, Brigade Surgeon Don, General Elkington, General Hall, and others. The corps, under the command of Mr. Cantlie, executed battalion movements with precision, and the stretcher drill was excellent. Seven companies were on parade, drawn up in the order of their enrolment—viz., Charing-cross, University, London, St. Bartholomew's, Middlesex, St. Thomas's, and Guy's. Two companies of the corps are going to take part in the Brighton review. One company, sixty strong, has volunteered its services for Egypt, but the Army Medical Department does not require their services at present.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN twenty-eight of the largest English towns 6189 births and 3779 deaths were registered during the week ending the 14th inst. The births were 375, and the deaths 152, above the average weekly numbers during 1884. The annual death-rate in these towns, which had not exceeded 21·4 and 20·6 per 1000 in the preceding two weeks, rose last week to 22·5. During the first ten weeks of the current quarter the death-rate in these towns averaged 22·5 per 1000, against 24·7, the mean rate in the corresponding periods of the nine years 1876-84. The lowest death-rates in these towns last week were 13·5 in Birkenhead, 15·5 in Portsmouth, 16·0 in Hull, and 16·8 in Brighton. The rates in the other towns ranged upwards to 27·6 in Newcastle-upon-Tyne, 28·6 in Manchester, 33·9 in Oldham, and 48·3 in Sunderland. The deaths referred to the principal zymotic diseases in the twenty-eight towns, which had been 377 and 395 in the previous two weeks, further rose to 398 last week; they included 129 from measles, 119 from whooping-cough, 41 from diarrhœa, 31 from scarlet fever, 31 from "fever" (principally enteric), 27 from small-pox, and 20 from diphtheria. No death from any of these zymotic diseases was recorded last week in Brighton; whereas they caused the highest death-rates in Bristol, Cardiff, and Sunderland. The highest death-rates from measles occurred in Huddersfield, Cardiff, and Sunderland; from whooping-cough in Preston and Bristol; from scarlet fever in Halifax and Wolverhampton; and from "fever" in Norwich. The 20 deaths from diphtheria in the twenty-eight towns included 8 in London, 3 in Liverpool, 2 in Nottingham, and 2 in Oldham. Small-pox caused 45 deaths in London and its outer ring of suburban districts, 3 in Manchester, 1 in Bradford, and 1 in Cardiff. The number of small-pox patients in the metropolitan asylum hospitals situated in and around London, which had declined in the preceding three weeks from 1223 to 988, further fell last week to 898; the cases admitted were 104 last week, against numbers declining from 255 to 94 in the previous four weeks. The Highgate Small-pox Hospital contained 92 patients on Saturday last, 16 cases having been admitted during the week. The deaths referred to diseases of the respiratory organs in London, which had been 384 and 374 in the preceding two weeks, rose last week to 455, but were 30 below the corrected weekly average. The causes of 96, or 2·6 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Bristol, Leeds, Leicester, and in three other smaller towns. The largest proportions of uncertified deaths were registered in Oldham, Hull, and Wolverhampton.

HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 24·6 and 22·8 per 1000 in the preceding two weeks, rose again to 24·4 in the week ending the 14th inst., and exceeded by 2·3 the mean rate during the same week in the twenty-eight large English towns. The rates in the Scotch towns last week ranged from 16·6 in Perth and 17·5 in Leith, to 24·3 in Aberdeen and 29·9 in Glasgow. The 595 deaths in the eight towns included 22 which were referred to whooping-cough, 22 to measles, 17 to diarrhœa, 13 to scarlet fever, 8 to diphtheria, 6 to "fever" (typhus, enteric, or simple), and not one to small-pox; in all, 88 deaths resulted from these principal zymotic diseases, against 82 and 71 in the preceding two weeks. These 88 deaths were equal to an annual rate of 3·6 per 1000, which was 1·3 above the mean rate from the same diseases in the twenty-eight English towns. The 22 deaths from whooping-cough showed an increase of 3 upon the number in the previous week, and included 9 in Glasgow, 4 in Edinburgh, and 4 in Leith. Of the 22 fatal cases of measles, 21 occurred in Glasgow. The 17 deaths attributed to diarrhœa also exceeded the numbers in recent weeks. Ten of the 13 fatal cases of scarlet fever and 5 of the 8 of diphtheria were returned in Glasgow. The 6 deaths referred to "fever" included 2 in Glasgow and 2 in Greenock. The deaths referred to acute diseases of the respiratory organs in the eight towns, which were 122 last week, were 5 above the number returned in the corresponding week of last year. The causes of 93, or nearly 15 per cent., of the deaths registered in the eight Scotch towns last week were not certified.

HEALTH OF DUBLIN.

The rate of mortality in Dublin, which had been equal to 30·3 and 32·7 per 1000 in the preceding two weeks, further rose to 39·5 in the week ending the 14th inst. During the first ten weeks of the current quarter the death-rate in the city averaged no less than 33·4 per 1000, the mean rate during the same period not exceeding 21·5 in London and 20·2 in Edinburgh. The 267 deaths in Dublin last week showed a further increase of 46 upon the high numbers returned in recent weeks, and included 11 which were referred to measles, 8 to "fever" (typhus, enteric, or simple), 5 to diarrhœa, 4 to whooping-cough, 2 to scarlet fever, and not one either to small-pox or diphtheria. Thus, 30 deaths resulted from these principal zymotic diseases, against 18 and 27 in the preceding two weeks; they were equal to an annual rate of 4·4 per 1000, the rate from the same diseases last week being but 2·1 in London and 1·9 in Edinburgh. The 11 fatal cases of measles in Dublin, which had been 8 and 10 in the previous two weeks, further rose to 11 last week. The 8 deaths from "fever," and the 5 from diarrhœa, also showed a further increase upon recent weekly numbers. The fatal cases of scarlet fever, on the other hand, were fewer than in any previous week of this year. Three inquest cases and 4 deaths from violence were registered within the city; and 94, or more than a third, of the deaths were recorded in public institutions. The deaths of infants showed an increase, and those of elderly persons considerably exceeded the numbers in any previous week of this year. The causes of 37, or nearly 14 per cent., of the deaths registered in the city last week were not certified.

HEALTH CONDITION OF SOUTHPORT.

A voluminous pamphlet has recently been published by Dr. Strethill H. Wright, the main object of which seems to be to warn the ratepayers of Southport that the vital statistics of that place issued by the sanitary authority are untrustworthy, and give a far too favourable impression of its sanitary condition. Dr. Wright asserts confidently that the present population of Southport is considerably over-estimated, the effect of which would undoubtedly be to under-state the death-rate. It would be out of place to attempt a discussion of the main point in dispute—namely, the present population of Southport; but some of the issues raised by Dr. Wright are of more than local interest, bearing as they do upon the construction of local vital statistics, and upon their value as a test of sanitary condition. We have often found reason to complain of defects in the reports of medical officers of health similar to those pointed out by Dr. Wright in the reports issued by Dr. Vernon, the medical officer of health for Southport. It is, in the first place, essential that the method employed for estimating the population of each sanitary district should be clearly described. Now it appears that the enumerated population of the Borough of Southport was 18,086 in 1871, and had increased to 32,206 in 1881, and Dr. Vernon's estimate for the middle of 1883 is stated to be 35,065. There can be no doubt that Dr. Vernon should describe his method of arriving at this estimate, which is clearly not arrived at by the Registrar-General's method of assuming that the rate of increase that prevailed between the last two censuses has since been maintained. The rate of increase of population in Southport during the last intercensal period was exceptionally large, and we are not in a position to support or to deny Dr. Wright's assertion that since 1881 there has practically been no increase, but all who are interested in the vital statistics of Southport are bound to know upon what principle the population of the borough is officially estimated. Dr. Wright next asserts that Dr. Vernon excludes from the mortality statistics of the borough the deaths of borough residents recorded in the Union Workhouse and in the Fever Hospital, both situated outside the borough. There can be no doubt that this is unsound both in theory and practice, and is none the more defensible because other reports than those of Southport err in the same direction. Another objectionable feature of the Southport reports, fairly criticised by Dr. Wright, is what Dr. Vernon calls the "local" rate, obtained by the elimination of a certain number of deaths, of "bad lives imported." For instance, it is stated that of 568 deaths in Southport in 1881, 106 were of persons said to have resided in Southport under one year:

Dr. Vernon, by some method of estimate not stated, concludes that 90 of these were of "bad lives imported," thus making a large reduction in the death-rate, but one which is open to grave objection. When Dr. Vernon leaves out of account the workhouse deaths belonging to his population and deducts a large proportion of deaths on very doubtful authority, he appears needlessly to invite incredulity as to the value of his statistics. Dr. Vernon is not alone in his attempt to improve his death-rate by a liberal correction for deaths of visitors. This is a tempting but a dangerous practice, and should at any rate not be attempted unless the method of correction is most precisely described. The importance of health reputation to Southport is so great, and the impossibility of constructing sound vital statistics without a trustworthy estimate of population is so patent, that the Town Council, as the sanitary authority of the borough, should be induced to undertake a local census, which has in other places been carried out at a very moderate cost.

THE SERVICES.

THE Army medical officers recently inspected, at Woolwich Arsenal, one of the two Döcker tent hospitals supplied for use in Suakim. These tents or huts are constructed by Messrs. Christoph and Unmack of Copenhagen, and appeared to meet the approval of the medical staff by their sanitary arrangements and general suitability for a hot climate. Each tent or hut is 72 ft. long by 20 ft. wide, its height being 13 ft. Each tent has accommodation for fifty patients, forty-four in two large wards at each end, and six in a private ward.

The Assistant Professorship of Surgery at Netley having been vacated by Surgeon-Major R. Tobin, who has been *ordered* on foreign service, the duties will for the present be performed by Surgeon-Major O. Codrington, M.D. It is understood that the appointment will be conferred upon Surgeon-Major C. H. Y. Godwin, late medical officer of Woolwich Arsenal, where he was very successful in applying the antiseptic system to the numerous severe injuries with which he had to deal.

Surgeon-General J. Irvine, Principal Medical Officer to the Army of Occupation in Egypt, has been selected for a similar position to her Majesty's forces stationed in Madras.

ADMIRALTY.—The following appointments have been made: Surgeon Francis G. Wright, to the *Bullfrog*; Charles G. Maclagan to be Surgeon and Agent at Berwick and Cheswick.

ARTILLERY VOLUNTEERS.—1st Norfolk: Acting Surgeon George Henry Cressey resigns his appointment.

RIFLE VOLUNTEERS.—1st Forfar (Dundee): Acting Surgeon William Gibb resigns his appointment.

Correspondence.

"Audi alteram partem."

CHLOROFORM *v.* ETHER.

To the Editor of THE LANCET.

SIR,—My attention has only just been called to a letter from Mr. George E. Walker of Liverpool in your issue of last week. In this letter Mr. Walker states, as his opinion, that in the production of complete anæsthesia there is little or no difference between chloroform and ether, whilst in the after-effects, especially as regards vomiting, nausea, and depression of spirits, chloroform is much superior to ether. Now, this is exactly contrary to what I have been endeavouring for years to demonstrate, and I cannot see on what grounds Mr. Walker bases his opinion, which I not only consider erroneous as to fact, but dangerous in the extreme. May I point out to him that the great difference between the two is that ether is a cardiac stimulant, whilst, on the other hand, chloroform is a depressor of the heart's action; that the former never kills by stopping the heart, whilst, on the contrary, the principal cause of death in fatal chloroform cases is the sudden cessation of the heart's action. I do not deny that dangerous symptoms occasionally arise during the administration of ether; but when these do occur the respiratory organs are affected and there is plenty of time for the proper application of remedies, these symptoms being rarely followed by death. In the fatal cases of chloroform administration death begins at the heart, and is instantaneous. If Mr. Walker consults the statistics of fatal cases, he will find that the proportion of deaths in chloroform administration is about 1 in 4500, whilst that of ether is only 1 in 20,000. Granted that there is more vomiting, nausea, and depression of spirits, even then I reply that these trifling ailments do not counterbalance the great advantage of the safety of the one anæsthetic over the other; moreover, I affirm that, if ether be rapidly given so that a small quantity suffices to produce anæsthesia, then the insensibility is not followed by those after-effects of which he complains.

I am not fond of rushing into print, but I plead as my excuse my sincere desire that your columns should not be the means of propagating the suggestion that chloroform is as safe to administer as ether.

I am, Sir, yours obediently,

Maddox-st., March, 1885. WOODHOUSE BRAINE, F.R.C.S.

"WHAT WAS THE CAUSE OF DEATH?"

To the Editor of THE LANCET.

SIR,—My attention has just been directed to Mr. Knight's communication in your issue of the 7th inst. In consequence of the tone of his letter, and of its many inaccuracies, I desire the privilege of stating my version of the case, and of placing before the profession some additional facts which were not mentioned at the trial.

At 10 P.M. on Jan. 5th I had an interview at the Southern Hospital with the senior house-surgeon and Mr. Knight, and I gave to Mr. Knight a letter which I had received from the solicitor for the defence, in which it was stated that I had the coroner's permission to examine the body of Johnson. Owing to the hesitation exhibited by Mr. Knight to permit the examination, I suggested that he should think the matter over, and I arranged to meet him at 11 A.M. on the following morning. I arrived at the hospital within five minutes of the time specified, and was informed by the porter that Mr. Knight had gone out. After some trouble I found Mr. Gordon, the senior house-surgeon, in one of the wards, and he kindly left his work and came to the post-mortem room, and remained with me during my examination of the body.

The following is a copy of Mr. Knight's depositions before the coroner: "Externally, I find on the top of the head two wounds, one of them an inch in front of the centre, and an inch to the right of the middle; it was pretty clean cut, but with slight contusion. It was a small wound half an inch long and a quarter of an inch deep. An inch behind and two inches to the right of this wound I found another wound similar in every respect to the first. There was a third cut on the chin over the lower jaw. This wound was in the shape of the letter Y, about three-quarters of an inch long by one-third of an inch in depth. I found some bruises; one over—i.e., above the left eye, and another just below or under the right eye. He had also an abrasion on the middle of the nose. The right eyeball itself was bruised. He had a slight abrasion of the fore or first finger of the right hand, and some blood on the other fingers. He had a small abrasion two inches below the right elbow. He had a little blood on the left hand, but no injury. On the right leg there was a small abrasion four inches below the knee. I have now described all the injuries to the deceased outwardly visible. On opening the body I found all the organs pretty healthy. There was slight congestion of all the organs, but their state was consistent with perfect health. There was no injury at all to the bones of the head or body. The cause of death in my opinion, judging from what I have heard to-day from the witnesses and from my post-mortem examination, has been concussion of the brain, due to the blows on the head. There was no natural cause present sufficient to account for death. The condition of the organs gave no indication at all of alcohol."—By Mr. Maddin: "The deceased's lungs were slightly congested. The heart was quite healthy. It is quite possible that if the deceased had been on a heavy spree of drink, the congestion of his lungs might be in consequence of that."

The following are extracts from my depositions before the coroner:—"I substantially agree with Mr. Knight's evidence as to the external injuries upon the deceased. I differ from

him as to the internal condition of the body. The main bloodvessel of the heart, the aorta, has extensive and long-standing disease. The left lung is almost completely semi-solid. The right lung is also extensively semi-solidified. I do not think the solidified condition of the lungs is due to post-mortem changes from lapse of time. I found all the organs well preserved, and quite fresh. I could not be positive as to the cause of deceased's death. In the absence of any injury at all the condition of the deceased's lungs would quite account for death. I would attach more importance to the butting spoken of than to any of the other injuries. A man in deceased's condition to receive a severe butt in the stomach would be likely to suffer from a serious nervous shock, which would affect the heart's action and accelerate death. In the condition of the deceased's heart and lungs the effects of struggling would be sufficient to cause death."

Additional facts and remarks.—A calcareous plate about an inch long was transversely embedded in the aorta embracing the openings of both coronary arteries. Yet Mr. Knight, in the coroner's depositions, says that "the heart was quite healthy," and makes no reference whatever to this condition of the aorta. After my evidence he appears before the magistrate, and in these depositions he says, "There was extensive degeneration of the aorta."

No section of any kind whatever had been made of the left lung when I examined it. This condition, as well as the calcareous plate, I pointed out to Mr. Gordon, and yet Mr. Knight informs us that "the examination occupied three hours, and every organ and every cavity was carefully examined," and that the honorary surgeon and Mr. Knight's two colleagues were present during that time. I confess I cannot believe that Mr. Gordon would spend three hours examining a body and neglect to examine one lung and make only one section through the other, which was distinctly diseased. Nor shall I believe that Mr. Little and Mr. Gordon will state that the lungs of the deceased were only "slightly congested," and that the condition of all the organs was consistent with "perfect health." Why did Mr. Knight secure at the assizes the services of his junior, Mr. Dixon, instead of his senior, Mr. Gordon? I know that an urgent message was despatched for Mr. Little, but he was indisposed, and unable to appear.

The deceased was forty years of age and kept a brothel. All the witnesses to the assault are unfortunates and lodged in his house. One witness speaks of blows by a belt buckle, another of a ginger-beer bottle, and a third of butting. On finding such a marked divergence of opinion between Mr. Knight and myself I caused the defence to make application to the coroner for him to appoint a distinguished member of the profession to examine the body before burial. I submitted the following list—viz., Mr. Rushton Parker, Drs. Alexander, Glynn, and Cameron. The coroner would grant permission, but would not authorise any of those gentlemen to act.

Mr. Knight summons both the judge and the jury to his aid in deciding the pathological differences between us. I have no objection to this rough appeal in the absence of a better one. The prisoners were arraigned on a charge of murder, and were found guilty of manslaughter and sentenced to eighteen months' imprisonment. From these facts Mr. Knight infers that the pathological points have been decided in his favour. I have no doubt the inference is quite as scientific as his evidence.

The scraps from the daily papers which he has interlarded his letter with and the learned discovery which he has so kindly communicated to me—viz., "That the heart and the aorta were not quite the same"—I must gratefully acknowledge as tokens of good taste.

I am, Sir, yours truly,

WILLIAM WHITFORD, M.D.,
Honorary Assistant Surgeon to Stanley Hospital, and Senior Assistant Surgeon to the Liverpool Cancer and Skin Hospital.

Shaw-street, Liverpool, March 16th, 1885.

HICKS *v.* BEDFORD AND OTHERS.

To the Editor of THE LANCET.

SIR,—I have no doubt that your attention has been drawn to this case, a full report of which appeared in last week's issue of *The Times*, and from which we find that in summing up the case the judge laid down a view of the law bearing on the admission to and detention of lunatics in the insane wards of workhouses which must come in the nature of a very disagreeable surprise to many masters, relieving officers and others, who have for many years past been in the habit of admitting and sending lunatics into workhouses for detention and treatment—especially in these days, when there are so many to be found ready and anxious to bring actions against all who have more or less unwittingly sinned against the provisions of the various statutes in that behalf.

Mr. Justice Wills is reported to have stated in his charge to the jury that "there is no statutory power whereby anyone, lunatic or otherwise, can be detained in a workhouse against his will," and the lunatic wards thereof can only be utilised for the temporary reception of persons in the receipt of in-door relief who become insane pending steps being taken to remove them to an asylum. Acting on this view of the law, the jury gave a verdict of £50 damages against Mr. Douglas, the master of the Marylebone Workhouse, and of £200 collectively against four others who had been made parties to the suit brought at the instance of the plaintiff Hicks, who it was shown had been suffering from delusions at the time of her removal to the Marylebone Workhouse.

Now, this view of the provision of the statute may be, and probably is, correct; but, if so, it has neither been so understood nor acted on, for it is only a very fractional number of the inmates of workhouse insane wards who find their way there from the body of the house; by far the greater proportion come from outside, and for convenience may be arranged under the following three heads:—

1. Undoubted paupers of whose insanity the relieving officer has obtained some idea of, and who are sent into the insane wards so that a medical examination might be made of their mental condition, and, if found to be deranged, with the view to their removal to an asylum.

2. Persons not paupers who are similarly sent in on the order of the relieving officer, or, it may be, taken there by their friends, with the view to their being sent to the county asylum, the friends paying for their maintenance, or for their being transferred to Bethlem or kindred establishments, or, it may be, to some private asylum, when their relatives are sufficiently well off to pay for their maintenance.

3. Cases brought by the police. These form by far the largest proportion, and they include every grade of society, as anyone conversant with workhouse management can testify to.

Now, this condition of things has gone on unchallenged for as long as I have had to do with medical relief to the poor, and that is upwards of forty years: and that such has been the practice cannot be denied either by the late Poor Law Commissioners, the Poor Law Board, by the present Local Government Board, or by the Lunacy Commissioners. But now we are suddenly pulled up by a judicial decision, that this procedure, which has acted beneficially in the past, is altogether illegal, and as a result thereof this verdict is come to.

It has been stated that the Lord Chancellor is about to bring in a Lunacy Act Amendment Bill. If he does, I trust that the influence of your journal may be brought to bear so that the framers of the Bill may make provision to deal with the admission to and detention of lunatics in workhouses a little more in accordance with common sense and the fitness of things than now holds good.

In conclusion, I am very pleased to state that the guardians of the Marylebone Workhouse have decided to pay Mr. Douglas's costs, &c. It is true that they could not well do otherwise, seeing that he has only carried out the practice which, to my personal knowledge, has been adopted in that workhouse for the last forty-seven years.

I am, Sir, yours obediently,

JOSEPH ROGERS.
Montague-place, Russell-square, March 11th, 1885.

THE CASE OF DR. BRADLEY.

To the Editor of THE LANCET.

SIR,—My attention has been called to the comments in the medical journals upon this case, and especially to a letter from Mr. Palmer, surgeon, of Whittington, which appears in THE LANCET of Jan. 31st last. As counsel for Dr. Bradley, my opinion that he was entirely innocent will probably carry little weight, but such nevertheless is my view; and the case is an illustration of the desirability of establishing without delay a Court of Criminal Appeal. However, I do not wish to enter upon that question now, nor into the facts

of this case, which seem to me to be accurately stated in the several articles and letters which have appeared upon this subject. Of course I was thoroughly aware that epileptics are frequently subject to delusions after a seizure; and this fact I was desirous of establishing before the jury. Unfortunately no scientific witnesses had been provided on Dr. Bradley's behalf, and therefore the only professional witness upon whom I could rely for information upon this subject was Mr. Palmer, who was called on behalf of the prosecution. I was told on the morning of the trial that he might be relied upon as a witness whose scientific views were in accordance with the theory of the defence, and therefore proceeded in cross-examination to approach the questions upon which I was desirous of eliciting information. A very few questions satisfied me that Mr. Palmer, from some cause or other—nervousness possibly—was what in legal circles would be called a "hostile witness"; and therefore, with the full concurrence of my experienced junior, Mr. Richard Harris, I determined to let Mr. Palmer leave the box and rest the case upon the improbability of the prosecutrix's story in preference to examining a witness of whose evidence I had no "proof," and whose answers seemed likely to be—to say the least—uncertain in their tendency. My recollection differs from Mr. Palmer's as to what he said about the duration of the fit, but I have no note of the evidence before me. I should not have troubled you with these observations but for the fact that Mr. Palmer seems to think that counsel did not sufficiently avail themselves of his valuable testimony. No one could regret more than myself and my learned friend that the evidence of an "independent witness" could not under the circumstances be made in the least degree available for the accused, and I regret now that the novelty, doubtless, of Mr. Palmer's position in the witness-box should have prevented him from making apparent that sympathy which we now know from his letter that he throughout felt for Dr. Bradley.

I am, Sir, yours faithfully,

Temple, March 11th, 1885. MARSTON C. BUSZARD.

INSTRUMENT FOR THE REMOVAL OF FALSE MEMBRANE AFTER TRACHEOTOMY.

To the Editor of THE LANCET.

SIR,—I wish to introduce to the notice of the profession an instrument I have devised for the purpose of relieving the dyspnœa, especially common in children, which is so often fatal in diphtheria, and which is caused by the false membrane acting as a plug in the air-passages and impeding respiration. It is for use in those cases where tracheotomy has been performed, and where for some reason the oiled feather will not do its work. It can be used at any period subsequent to the operation without removing the tracheotomy tube. It does its work by suction.

The instrument consists of a glass tube, 1½ in. in superficial diameter for a child and 2¼ in. in length. The opening at one end is free, and the tube is here shaped at its edge so as to fit the convexity of the throat. The other end is closed by a metal cap, from the centre of which projects a metal tube, about 1¼ in. long, communicating with the interior of the glass tube. A piece of indiarubber piping about a yard in length is fitted tightly on to the metal tube. When it is wished to aspirate the trachea, the free end of the glass tube is placed over the tracheotomy wound, leaving a margin of skin between the edge of the tube and the incision all round. The tracheotomy tube is not withdrawn. Suction is applied to the free end of the indiarubber piping by means of the exhausting syringe which goes with the instrument. By these means a partial vacuum is made in the glass tube, and it adheres to the skin by atmospheric pressure. Air rushes up from the lungs through the tracheotomy tube to restore equilibrium, and the obstruction is carried along with it.

By the kind permission of Dr. Moore and Mr. Bowlby several experiments have been tried with the instrument in the post-mortem room at St. Bartholomew's Hospital, at which place I am a student. Two instances will suffice. In one case I injected about an ounce of vaseline and zinc ointment into the trachea of an adult, having previously done tracheotomy. A rather larger syringe than the one now with the instrument was used, and most of the substance injected came up through the tracheotomy tube (which was tied in) at the first stroke of the syringe. On continuing to work the syringe, the rest quickly followed. On opening the trachea it was found empty, with the exception of a small quantity of the substance, which had lodged in the upper part above the tube; some was also found in the divisions of the bronchi. In the second case, also that of an adult, the syringe used was the one now with the instrument. About three-quarters of an ounce of vaseline and zinc was injected. Two or three strokes of the syringe brought up this, which was followed by about four ounces of bloody fluid, which had flowed down into the trachea from a fractured base of the skull. The glass tube of the aspirator was filled, and about half filled a second time with this fluid. The syringe was worked pretty vigorously. On opening the trachea it was found empty. The instrument has also been experimented with in the case of a child who had died in the hospital, with similar results.

I remain, Sir, yours sincerely,

BERTRAND SHADWELL.

Bernard-street, Russell-square, Feb. 25th, 1885.

NORTHERN COUNTIES NOTES.

(From our own Correspondent.)

COLLIERY EXPLOSIONS AND THEIR CAUSES.

THE recklessness displayed by miners was well pointed out the other day at the Durham County Police-court, when two lads were charged under the Mines Regulation Act with wilfully damaging a safety lamp in one of the mines in the district. The lads, it appeared from the manager's statement, who prosecuted, had taken a plate-nail and shaped it like a key; they then opened the lamp, took the wick out, and also the gauze off the lamp. The lives of about 300 men and boys were in danger through their reckless act, and it is no wonder that the manager wished them to be flogged if the law would permit, as fining them would only punish the parents. They got off, however, with a fine of five shillings, the magistrates leaving the flogging to "the discretion of the parents." Concerning the late sad disaster at Usworth, a correspondent writes to our papers to say that he cannot understand why our colliery engineers do not use Fleuss's apparatus when exploring the mines after an explosion, and points out in support of his view that at the meeting of the British Association at Montreal Mr. J. Clarke Hawkshaw, the engineer of the Severn Tunnel, described the explorations made when the tunnel was flooded in the following words: "To still further reduce the flood of water, an attempt was made by divers to shut a door across the drifting under the Severn about 330 yards from the bottom of the shaft, and thereby cut off the water flowing into the long driftway under the river. Divers in the ordinary dress failed to reach the door, but one, named Lambert, volunteered to go to it alone with Fleuss's apparatus. He succeeded in reaching the door and closing it, being under water without any communication with those above for one hour and twenty-five minutes." Mr. R. S. Newall of Gateshead, who writes the letter I refer to, says, "If a man can remain so long under water without any communication with the outer world, he can certainly walk more easily through an atmosphere of carbonic acid, and without the assistance of a mouthful of nails!—which, by the way, is one of the most ridiculous experiments I have read of for many years." Mr. Newall points out that every colliery ought to have several Fleuss's apparatus at hand, and that many a life would be saved if they were used.

A NEW AMBULANCE LITTER.

Mr. Robert H. Mushens, Secretary to the Sunderland Provident Dispensary, and the inventor of an ambulance emergency case which has met with considerable acceptance in many parts of the country, has just completed an ambulance litter which can be used in conjunction with or separately from the ambulance case. It consists of two brass tubes closed at the ends, eight feet in length. These are kept in position by two crossbars with hooks at each end, and secured with set screws. A piece of tarpaulin six feet in length runs between the crossbars, to one of which a pillow is attached, and two shoulder-straps or slings complete the arrangement.

THE CARRIAGE TAX.

The agitation against the continuance of the carriage tax has been taken up and carried on with much spirit and determination in the north of England. I have just seen a circular letter addressed to each member of the House of

Commons by Mr. John Philipson, the chairman of the movement here, in which the objections to the tax are forcibly and ably set forth. The matter is one which directly affects a large proportion of our *confrères* here and elsewhere over the country; so it is to be hoped that the efforts of Mr. John Philipson and others who are working so hard on the subject may be soon crowned with success.

THE DISTRESS IN THE NORTH.

At last there is a rift in the cloud which has so long hung over our industrial centres in the north. At Sunderland the returns showed a weekly decrease of 156 families on the distress fund. In Newcastle and Gateshead large numbers of working men are obtaining employment, and, the weather being very favourable, it is supposed that the relief operations may be soon brought to a close.

SUNDERLAND MORTALITY.

The death-rate in Sunderland last week was 48·1 per 1000, 116 deaths having occurred. In the previous week the death-rate was 41·9; in the corresponding week of last year it was 28·2. Last week there were forty-five deaths from measles, and fifteen suspected to have been caused by the disease, representing a death-rate from that cause alone of 24·9. The death-rate from ordinary causes was 23·2 per 1000. Since the commencement of the epidemic in January there has been a total of 217 deaths.

Newcastle-upon-Tyne, March 17th.

IRELAND.

(From our own Correspondent.)

ROYAL UNIVERSITY OF IRELAND.

IT is generally conceded that this University should, from the large number of its graduates, including those of the late Queen's University, possess one or two members to represent it in Parliament. It is probable that the subject will be ventilated in the House of Commons by Dr. Lyons, M.P. for Dublin, who, it is stated, has received promises of support from both Liberal and Conservative members of the House. One important fact should not be lost sight of—viz., that the number of graduates of the Royal University exceeds that reached by the London University in 1875, when that institution was accorded representation in Parliament.

JERVIS-STREET HOSPITAL, DUBLIN.

The additions to this hospital are now almost complete, and it is rumoured that a probability exists that H.R.H. the Prince of Wales will formally open the new building during his visit to Dublin early in April. The building has a frontage of 167 ft. by 100 ft. in height, and is substantially constructed. On the ground-floor, and the three storeys above, the wards are situated. It is furnished with staircases at either end, extending to the terraced roof, united to each other by glass corridors on each storey. The four main wards are of considerable extent, and the ventilation is on the most approved principles. A peculiar feature exists in the arrangement of the roofs of the buildings, which are flat, asphalted, and surrounded by a balustrade, so as to form a terrace for use by convalescent inmates of the hospital. From each storey access is obtained to the roof by means of a hydraulic lift. The cylinder which works the car can raise a load of 1200 lb., 154 gallons of water being used in raising that weight 75 ft. It is intended to extend the northern and southern wings eastward at some future date, arrangements for this purpose having been prepared in the designs for the completion of the hospital buildings.

CORK FEVER HOSPITAL.

During last year, although about thirty more cases of scarlatina, as compared with the previous year, were admitted, not a single death from this disease took place in this hospital. The mortality from typhus and enteric fevers amounted to 4 per cent., and from pneumonia 3·1—results which will compare favourably with those of any institution of a similar kind.

SIR PATRICK DUN'S HOSPITAL, DUBLIN.

The governors of this hospital are anxious to erect on the hospital grounds a detached building for the treatment of fever, small-pox, cholera, and other infectious diseases, and have commenced a subscription list for the purpose, contributions to which they solicit.

THE CONVALESCENT HOME, STILLORGAN.

This valuable institution has existed for seventeen years, but for the last few years the accommodation it provided has been found to be most inadequate. The Committee accordingly advertised for tenders for additions to the hospital, and ultimately accepted one amounting to £2200. The additional buildings are now nearly complete, while the building of the Napier wing, commenced at the same time, has made satisfactory progress, and when finished will add a new feature to the institution by extending its advantages to those who are in a position to contribute towards the expenses of their maintenance. Dr. Denham, one of the visiting physicians, having retired from practice, the vacancy has been filled by the appointment of Dr. Richard A. Hayes.

NATIONAL EYE AND EAR INFIRMARY.

During last year in the Dispensary for Diseases of the Throat, which was established two years since as an adjunct to the Ear Department, 131 new patients were treated, of whom a large proportion consisted of aural patients who were found to have throat complications. Both in the wards and the extern department the numbers obtaining advice have greatly exceeded former years, but the number of annual subscribers have not increased as could be wished.

On the 10th prox. his Royal Highness the Prince of Wales will lay the foundation stone of the New Science and Art Museum and National Library, Dublin. The buildings will cover an area of about one acre and a half, and the estimated cost will be £120,000.

Dr. Norman, late resident physician of Castlebar Lunatic Asylum, has been presented with an address and testimonial from the staff of that asylum, on his transference to the Monaghan Asylum.

Dublin, March 17th.

PARIS.

(From our Paris Correspondent.)

THE DIVULGENCE OF PROFESSIONAL SECRETS.

I ALWAYS understood that the divulgence of a professional secret constituted a criminal offence only when accompanied by evidence of malice; but the following example would seem to show such a conclusion to be erroneous. It may be recollected that after the death of the celebrated painter, Bastien-Lepage, which took place about the 12th of December last, several articles were published in the daily papers reporting the circumstance, in doing which the most uncharitable insinuations were made in some of them as to the nature of the malady from which the deceased suffered. After reading these reports, Dr. Watelet, his medical attendant, sent a letter to a morning paper to refute them, and at the same time mentioned that his patient died from a cancerous affection. This aroused the indignation of the judicial authorities, in consequence of which Dr. Watelet was sued before the Correctional Court last week. The judge admitted that the intention on the part of the defendant was praiseworthy, yet, as the act constituted a breach of the penal code, he was condemned to pay a nominal fine of 100 francs, and the editor of the paper in which Dr. Watelet's letter appeared was fined 16 francs for complicity. This case and the following prove how extremely difficult and delicate is the position of a medical man in his relations to society. About thirty years ago Dr. Delpech, a celebrated physician of Montpellier, was assassinated by one of his patients under the following circumstances. The Doctor having learned that his patient, who was suffering from a contagious malady, was engaged to be married to a young lady, the daughter of an intimate friend of his, advised him to discontinue his addresses, and threatened that if he persisted in his intentions he would expose the nature of the malady to the parents of the young lady. This, however, had no effect on the young man, and Dr. Delpech, seeing that his remonstrances were of no avail, informed the parents of the disease from which their intended son-in-law was suffering, in consequence of which the marriage was broken off. The young man, irritated, went to the Doctor's house and shot him dead. He was arrested, and tried before the Supreme Court, but acquitted.

RETIREMENT OF PROFESSOR BOUCHARDAT.

Dr. Bouchardat, Professor of Hygiene at the Paris Faculty of Medicine, has, after a service of nearly forty years, retired, and his name is transferred to the list of Honorary Professors.

Paris, March 17th.

MEDICAL NOTES IN PARLIAMENT.

The Poisons Bill.

IN the House of Lords on Thursday, the 19th inst., Lord Carlingford moved the second reading of the Poisons Bill, stating that it was an effort in the direction of providing protection for the public, which the present law did not provide. He did not think the objects aimed at by this measure could be attained by any amendment of the present law, against which many and continual complaints had been made to the Home Office. The Bill, in addition to many precautions necessary under the present Acts, added new clauses—among others the labelling of every poison sold, with name and address of the seller; that every person selling a poison must be a chemist and druggist or a medical practitioner; and that poisons could not be sold to persons under sixteen years of age. Other restrictions would be applied to the most virulent class of poisons: the buyer must be known to the seller, or introduced to him by someone with whom he is acquainted, and the seller must record every transaction on forms prescribed. With regard to patent medicines, a person selling any compound of that class, whether it bore a stamp or not, would have to take his chance as to the way in which he sold it. If he believed it innocuous within the meaning of the Act, and sold it as such, he would run the risk of penalties if in any case a medicine had been proved by judicial investigation to be a poisonous compound, and such medicine would be then included in the list of poisons. The Bill was read a second time.

St. Pancras and its Medical Officer.

In the House of Commons on the 13th inst., Mr. Russell, in reply to Mr. Firth, who asked whether Dr. Murphy's resignation as medical officer of St. Pancras was due to exceptional and discreditable means adopted to discredit him in his contest with those who were affected by his condemnation of insanitary property in St. Pancras, and whether the Local Government Board proposed to take any steps in the matter, said he understood Dr. Murphy had discharged his duties with great efficiency. The action of the local authority in this matter was in no way subject to the jurisdiction of the Local Government Board, which could not interfere.

Patent Medicines.

On the 16th inst. Mr. Puleston asked the Chancellor of the Exchequer whether his attention had been called to an article in THE LANCET on this subject. The matter is referred to in another column.

The Cheltenham Medical Officer of Health.

In reply to Mr. J. Campbell, Mr. G. E. Russell said that the Town Council of Cheltenham last month appointed to the office of medical officer of health a gentleman who at that time possessed a surgical qualification only. He had since obtained a medical qualification. The appointment was not reported to the Board within the time required by the regulations. The Board have asked for particulars as to the appointment, but seeing that the gentleman elected has now both a medical and a surgical qualification, the Board would not regard the fact that at the time of election he had one qualification only as being in itself a sufficient ground for withholding their sanction to the appointment.

The Royal Infirmary, Dublin.

On the 17th inst., in reply to Mr. Eaton, the Marquis of Hartington stated that during the first week of March two deaths occurred in the Royal Infirmary, Dublin. According to the latest returns, there were on duty in this hospital one surgeon-major in charge, four civilian surgeons, one sergeant of the Medical Staff Corps, with orderlies from Line regiments. It is quite true that under the former system the hospital orderlies would have been drawn from the regiments, and that they would have had a certain amount of hospital training, though far less than is now given to men of the Medical Staff Corps. Under that system during war the regimental hospitals at home would have their own orderlies; but in the field the trained orderlies would have had to be largely supplemented by untrained men, on whom the base hospitals would probably have entirely depended.

The Case of Mr. Charles Hillman.

In reply to Mr. W. Corbet, Mr. H. Fowler stated that the Secretary of State has called the attention of the Commissioners in Lunacy to this case, and they have reported to him that, after consideration, it appears to them that certain persons have been concerned in the unlawful taking and confinement, as an insane patient, of Mr. Charles Hillman; but they are of opinion, having before them the certificates of three medical men and the statement of the medical superintendent of the Lunatic Asylum for the county of Sussex, that Mr. Charles Hillman was in fact insane, and a proper person to be placed under care and treatment; and finding no evidence of malice or bad faith on the part of any of the persons referred to, they do not consider that a *primâ facie* case exists for the prosecution of such persons.

The Reception of Persons of Unsound Mind into Workhouses.

Earl Percy has given notice of his intention to ask whether the attention of the Local Government Board has been called by the guardians of the Westminster Union to the recent decision of Mr. Justice Wills, in the proceedings lately taken against the master of Marylebone Workhouse and other officials of that union, with regard to the reception of persons of unsound mind into workhouses, and whether the President proposes to issue any instructional letter to the masters of workhouses generally and relieving officers as to their duty in the matter; and whether it is proposed to introduce any measure for the amendment of the law relating to the reception of supposed insane persons into workhouses, and for protecting Poor-law officials from the responsibilities in which they may be involved by the strict application of Mr. Justice Wills's decision.

Obituary.

EBENEZER PYE-SMITH, F.R.C.S.

MANY old Guy's men will have been reminded of their early associations in seeing the announcement of the death, at a good old age, of Mr. Pye-Smith. Though retired from practice for more than ten years, he was closely connected with the traditions of that hospital and medical school.

The son of the Rev. John Pye-Smith, a theological writer and a Fellow of the Royal Society, whose name is still held in esteem, he inherited a love of knowledge, habits of industry, and deep religious principles. Having completed his course at Mill-hill School, at the age of eighteen he became a pupil of the Borough Hospital, and afterwards studied in Paris. Returning to England about 1830, Mr. Pye-Smith settled in the City, and soon afterwards married the lady who now survives him. He took pupils during the earlier part of his career, and between 1840 and 1850 had the discernment to send them up to the examinations of the then new University of London. Here they obtained remarkable successes, and he had the perhaps unexampled satisfaction of seeing not less than five of them, Dr. Oldham, Dr. Habershon, Dr. Pavy, his own son, Dr. Pye-Smith, and the late Dr. J. J. Phillips, in the position of physicians to the great hospital which he was proud to call his *alma mater*. After giving up practice he wisely travelled in Italy for more than a year, "to learn how to be idle," and after a short trial of Kensington, bought a house and garden at Sevenoaks, where he spent the last ten years of his prolonged life in peaceful but not inactive retirement.

Gifted with remarkably fine features, of tall and slender figure, with the courteous manners of the old school and the frank simplicity of a guileless nature, Mr. Pye-Smith was in all outward respects fitted to win confidence, while his insight and judgment, his skill in withholding, no less than his energy in enforcing, active treatment, and his unaffected sympathy with suffering confirmed him in the esteem of his patients. Those who knew him believe that his defects were giving too long time to individual cases and over-anxiety about results. The one made his work more laborious than was needful, and the other too often disturbed his peace. The large number of old patients who flocked to the funeral when Mr. Pye-Smith was laid to rest at Abney Park Cemetery, in the neighbourhood where the last twenty years of his professional life was passed, proved how lasting

was the memory of his skill and devotion. He was followed to the grave by his old friend, and the son of his father's friend, Sir Risdon Bennett; by his former pupil, Dr. Habershon; by Dr. Payne of St. Thomas's Hospital; by his fellow student, Dr. Lockhart, late of Pekin; by his five sons, two of them holding hospital appointments; Dr. Gilbert of Clapton, his successor in practice; Dr. Fotherby of Finsbury-square; Dr. Dubson, R.N., of Trinity-square; and Dr. Burchell of Stoke Newington.

His life is an example of how much happiness and respect and more than money's worth is within the reach of the medical practitioner who seeks to do well rather than to do much, whose ambition is moderate but his aims high, and whose entire course from earliest youth up to extreme old age is one of unselfish devotion to duty,

"As ever in the great Taskmaster's eye.

Medical News.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on the 12th inst.:—

Aldous, George Frederick, St. Bartholomew's Hospital.
Collinson, Thomas Arthur, King's College.
Ellison, Ernest Henry, King's College.
Hickey, Evan Lewis, King's College.
Raw, William Edmund St. Michael, London Hospital.

DR. BODKIN, of Chelmsford, has been recommended by the House Committee of the Infirmary of that town to fill the post on the staff rendered vacant by the lamented death of Mr. D. M. B. Wheeler.

DR. JOSIAH WILLIAMS, of Sheffield, intends forwarding a parcel of books and newspapers for our soldiers in the Soudan every week, and will be glad to receive contributions of suitable literature.

A SERIOUS epidemic of whooping-cough has ravaged the islands of Suva, Fiji. The malady has carried off all the very young native children, and left a decrease in the population on the year of 3000.

INTERNATIONAL INVENTIONS EXHIBITION.—H.R.H. the Prince of Wales, President of the International Inventions Exhibition, has fixed Monday, May 4th, for the opening of the Exhibition.

A CHELMSFORD paper mentions that the town seems to be attracting to itself quite an influx of fresh medical practitioners, no less than four having recently taken houses or arranged to do so.

PROFESSOR F. S. B. F. DE CHAUMONT, M.D., F.R.S., has accepted the presidentship of the Autumn Congress of the Sanitary Institute of Great Britain, to be held in Leicester from September 22nd to 26th inclusive.

MANCHESTER HOSPITAL SUNDAY AND SATURDAY FUNDS.—The amount paid into the bank to the credit of the Hospital Sunday Fund up to the present time is £4716 16*s.* 6*d.*, and to that of the Hospital Saturday Fund, £2780 19*s.* 5*d.*, the two sums making a total of £7497 15*s.* 11*d.*

FROM the report of the Committee of the Manchester and Salford Day Nurseries Association, it appears that during last year 4319 attendances were made at the two nurseries superintended by the Association. The income amounted to £212, leaving a surplus of £10 over the expenditure.

ON the 16th inst., it was decided in the Queen's Bench Division, in the case of Page *v.* Harrison, that the defendant was entitled to a new trial, which was accordingly granted. It will be remembered that the plaintiff, who is a medical man, obtained a verdict some months ago of £150 against the defendant for slander.

PROPOSED REMOVAL OF ST. LUKE'S HOSPITAL.—An application has been made to the churchwardens and overseers of the parish of St. Luke, on the part of the inhabitants, to join in a memorial to the authorities of St. Bartholomew's Hospital for the removal of St. Luke's Hospital from Old-street to Dulwich; the request, however, has not been acceded to.

MR. GEO. JOHN IAGO has been appointed Secretary and Librarian to the Westminster Hospital Medical School.

THE SEWAGE OF COVENTRY.—The Town Council have recently decided, in order to meet the increase in population, to considerably enlarge the sewerage works of Coventry. The sewage has for the past ten years been dealt with by a combined system of chemical precipitation and filtration through land, and the operations have given general satisfaction.

ROYAL ASYLUM OF ST. ANNE'S SOCIETY.—The Council of the Royal Medical Benevolent College are about to nominate the orphan daughter of a medical man to one of the perpetual presentations to the Royal Asylum of St. Anne's Society which have been placed in their hands. Immediate application should be made to the Secretary at the office in Soho-square.

DR. HENRY TOMKINS, on the occasion of his leaving the Monsall Fever Hospital, in connexion with the Royal Infirmary, Manchester, to which institution he has acted as resident medical officer for the last six years, was entertained at dinner on the evening of the 6th inst., at the Albion Hotel, Piccadilly, by a few of his friends and old fellow-students. V. A. Wartenberg, Esq., of Blackpool, was in the chair.

THE POPLAR HOSPITAL FOR ACCIDENTS.—The annual meeting of the subscribers to this institution was held on the 18th inst. The number of in-patients admitted during the past year was 612, and the out-patients treated were 7289. The total receipts amounted to £3624, and the expenses to £3054. It was decided that the committee should contribute £150 towards the expenses of a Convalescent Home at Southend.

AT the West Ham Police-court on Wednesday, March 18th, the medical officer of health for the Port of London applied for an order from the presiding magistrate for the destruction of forty-five tons of beef and a number of pigs, partridges, turkeys, &c., on the steamship *Newcastle City*, lying in the Victoria Docks. The vessel soon after leaving port met with very heavy weather, which necessitated putting back, and in consequence of this lengthening of the voyage the meat had decomposed.

MEDICAL OFFICERS OF HEALTH ASSOCIATION.—The annual meeting of members of the North-Western Association of Medical Officers of Health was held in Manchester on the 12th inst. It was stated that during the past year three new names had been added to the list of members. There are now thirty-three ordinary members, twenty-six associates, and four honorary members. In view of these figures, the committee strongly urged upon those connected with the Association the duty of making its objects more widely known. Dr. T. W. Hime was elected president for the ensuing year.

THE HAMPSTEAD SMALL-POX HOSPITAL.—At a meeting of the Hampstead Small-pox Hospital Removal Committee on the 14th inst., a letter from the Local Government Board was submitted in reply to a request that Sir C. Dilke would receive the deputation appointed at the great meetings recently held under the chairmanship of the Lord Lieutenant of Middlesex. The Board state that they will, on receiving a copy of the committee's memorial, consider whether they will grant an interview to the deputation, and it was resolved that the memorial should at once be prepared and forwarded.

MR. WALTER WHITE.—The retirement of Mr. Walter White from the assistant-secretaryship of the Royal Society, after forty years of faithful service, is an event that will be regretted by many members of the profession who hold the blue riband of the Society, as well as by the Fellows at large. The post of assistant-secretary is one of great responsibility, demanding incessant attention to details, and delicate management. In Mr. White the ability required for the task has been pre-eminent. Though it is not generally known, Mr. White is a poet as well as a scholar. In his exquisite ballad "The Prisoner and his Dream," he has translated the immortal "Progress" into verse; and in a volume of beautiful poems has depicted some fine scenes from the haunts of continental travel in which he has passed his hours of holiday. We trust, therefore, that what the Royal Society loses the world may gain in more ambitious literary ventures.

PROPOSED PARK AT DULWICH.—At a public meeting held in the Lambeth Vestry Hall on the 12th inst. the following resolution was carried:—"That this public meeting of the inhabitants of the parish of Lambeth supports the action of the estates governors of Dulwich College with respect to the proposed grant of seventy-two acres of land for the benefit of the inhabitants of South London, and that a copy of this resolution be sent to the governors."

IRISH GRADUATES' ASSOCIATION.—The dinner in connexion with this Association was held on the 17th inst., at the Holborn Restaurant, when sixty-six members and guests were present, amongst whom were Professor Stokes, M.D., F.R.C.S.I., Dr. H. Macnaughton Jones, Sir William MacCormac, Dr. Richard Quain, Mr. Savory, Dr. Playfair, Mr. Timothy Holmes, Mr. Jonathan Hutchinson, Dr. Crawford, Director-General A.M.D., and Dr. Frederick Roberts. During the evening nearly a score of new members joined the ranks of the Association.

LEEDS GENERAL INFIRMARY.—At the annual general board of governors of this institution, held on the 4th inst., it was stated that the number of patients admitted during 1884 was the highest in any one year since the opening of the infirmary—viz., 23,075. The number of in-patients admitted was 3807, against 3551 the preceding year, showing an increase of 256; and the number remaining in the infirmary on December 31st, 1883, was 233, making a total of 4040 treated during the year. The daily number of beds occupied was 230, and the average duration of treatment of each patient was twenty-one days. The rate of mortality was 5·43 per cent. The receipts for 1884 amounted to £16,102, as against £15,326 for 1803; and the expenditure to £14,316, as against £14,634.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—The sixth meeting of the twenty-ninth session, 1884-85, was held at the Royal Kent Dispensary, Greenwich-road, on Friday evening, March 6th, 1885, at 8 o'clock precisely, when the following gentlemen were balloted for:—Charters James Symonds, F.R.C.S., John Poland, F.R.C.S., Edmund Samuel Dashwood, M.R.C.S., L.S.A. Mr. Charters James Symonds read a paper "On the Employment of Simple Pressure in the Treatment of Acute and Chronic Diseases of the Joints;" T. Moore, F.R.C.S., Surgeon to the Miller Memorial Hospital, exhibited a case of an unusual form of Imperforate Anus; Dr. Ernest Clarke exhibited some specimens of Tumour of the Testis and Diseased Placenta, with microscopic sections of the same.

THE STATE OF THE THAMES.—At a conference of representatives of vestries and district boards of works, called by the vestry of St. George, Hanover-square, to consider the state of the Thames, the following resolutions were carried unanimously:—"That this meeting is of opinion that the evils of the present system of discharging the metropolitan sewage are such as to require a remedy, and that it is in the public interest that a remedy should be applied with the least possible delay;" and also, "That this meeting, having heard with great pleasure that experiments are now being made by the Metropolitan Board of Works at Crossness, do adjourn the further consideration of the question until the St. George's, Hanover-square, representatives think it desirable to call a further meeting of the delegates."

Medical Appointments.

Intimations for this column must be sent DIRECT *to the Office of* THE LANCET *before 9 o'clock on Thursday Morning at the latest.*

BARRITT, GILBERT LACY, L.R.C.P.Lond., M.R.C.S., has been appointed Assistant Medical Officer to the Crumpsall Workhouse, Manchester Township, vice Winder, resigned.

BROWN, JOHN HENRY, M.B., C.M.Ed., M.R.C.S., has been appointed Assistant Medical Officer to the Crumpsall Workhouse, Manchester Township, vice Richmond, resigned.

BROWNE, EDWARD GEORGE, L.R.C.S.I., has been appointed House-Surgeon to the City of Dublin Hospital.

BYLES, HENRY, M.B., C.M.Ed., has been appointed Medical Officer of Health for the Sanitary District of Eccleshill, near Bradford, Yorks, vice Aston, resigned.

CALLAGHAN, JAMES LESLIE, L.R.C.S.I. & L.R.C.P.Ed., has been appointed Medical Officer of the Easingwold Union District.

CROPLEY, HENRY, M.R.C.S., L.S.A.Lond., has been appointed Medical Officer for the Buckland District of the Tavistock Union, vice Butters, resigned.

FOXWELL, ARTHUR, B.A., M.B.Cantab., M.R.C.P.Lond., has been appointed Assistant-Physician to the Birmingham General Hospital.

GARNHAM, G. J. WATERS, L.R.C.P.Ed., L.R.C.S.Ed., has been appointed Medical Officer to the Chippenham District of the Chippenham Union, vice Francis Spencer, F.R.C.S., L.S.A.Lond., resigned.

HILL, P. E., M.R.C.S., L.S.A. Lond., has been appointed Civil Surgeon to Her Majesty's Ordnance Survey for the Crickhowell District.

JOHNSON, HERBERT, L.R.C.P., L.R.C.S., has been appointed Medical Officer of Health for the Borough of Whitby (Whitby Urban Sanitary District); also Medical Officer of Health for the Whitby Rural Sanitary District.

LEE, HERBERT GROVE, M.D. St. And., M.R.C.S., L.S.A.Lond., has been reappointed Medical Officer for the Haddenham District of the Aylesbury Union.

MORTON, SHADFORTH, M.D., M.R.C.S., has been appointed Surgeon to the Croydon General Hospital.

RICE, EDWARD, M.B.Lond., M.R.C.S., has been appointed House-Physician to the Radcliffe Infirmary, Oxford, vice Harris, resigned.

ROWLANDS, WILLIAM, L.K.Q.C.P.I., M.R.C.S., has been appointed Medical Officer for the North Sefton District of the West Derby Union, vice May, deceased.

RUGG, GEO. LEWIS, M.R.C.S., L.S.A.Lond., has been appointed Assistant Medical Officer and Dispenser to the Lambeth Infirmary and Workhouse, vice Roberts, resigned.

STEPHENSON, SYDNEY H. A., M.B.Ed., has been appointed Resident Medical Officer to the Rochdale Infirmary, vice W. Piercy Fox, resigned.

TAYLOR, EDWARD MUSCROFT, L.R.C.S., L.R.C.P., has been appointed Medical Officer to the Workhouse, Whitby; Medical Officer to the East Side District, Whitby; and Public Vaccinator for Whitby and District.

Births, Marriages, and Deaths.

BIRTHS.

BIGGS.—On the 9th inst., at Hillside, Child's-hill, N.W., the wife of John M. Biggs, Surgeon, of a son.

KING.—On the 15th inst., at Sutton-court-road, Chiswick, the wife of William Moore King, M.R.C.S., of a daughter.

MANSON.—On the 30th Jan., at Hongkong, China, the wife of Dr. Patrick Manson, of a daughter.

O'CONNELL.—On the 16th inst., at North Villa, Havelock-park, Southsea, the wife of Surgeon-Major E. O'Connell, Army Medical Department, of a daughter.

MARRIAGES.

CLAREMONT—HELMORE.—On the 9th inst., at Holy Cross Church, Crediton, Constantine Cecil Claremont, M.R.C.S., second son of Claude Clarke Claremont, M.R.C.S., L.S.A.Lond., of Millbrook House, N.W., to Jessica, second daughter of Frederick Helmore, Esq., of Taw Vale, Crediton, Devon.

GLYNN—GRIFFIN.—On the 12th inst., at Christ Church, Linnet-lane, Liverpool, T. R. Glynn, M.D., of Liverpool, to Alice Lewtas, daughter of the late Henry Griffin, of Grove-park, Liverpool.

JONES—SMITH.—On the 12th inst., at St. Andrew's, Haverstock-hill John Evans Jones, M.D., to Jessie Kate, eldest daughter of William Smith, Esq., Head Master Orphan Working School, Maitland-park, N.W.

DEATHS.

BARKER.—On the 31st Jan., at Alma-road, E., St. Kilda, Madeline Charlotte Skene, wife of Edward Barker, M.D., 53, Latrobe-street, Melbourne, and eldest daughter of the late Alexander Scott, Esq., Trinity, N.B.

CHRISTIE.—On the 13th inst., at South-street, St. Andrews, Scotland, Alexander Christie, Surgeon Bengal Medical Service, Retired List.

COLVILL.—on the 13th inst., at Lawton, Forfarshire, N.B., William Henry Colvill, Brigade Surgeon Her Majesty's Indian Army, Bombay (retired). Friends will please accept this the only intimation.

MAKENS.—On the 14th inst., at the residence of his brother, Colney, Norwich, John Makens, M.B.Lond., late of Middleton, Teesdale, third son of Robert Makins, of Ringshall, Suffolk, aged 44.

MASON.—On the 18th inst., Dr. Mason, F.R.G.S., of 182, Lewisham High-road, and 44, Finsbury-circus.

MILLER.—On the 17th inst., at Eye, Suffolk, Emily, the wife of W. W. Miller, M.D., aged 54.

N.B.—*A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.*

Medical Diary for the ensuing Week.

Monday, March 23.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10.30 A.M. each day, and at the same hour.
ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M. each day, and at the same hour.
ST. MARK'S HOSPITAL.—Operations, 2 P.M., and on Tuesdays at the same hour.
HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.
METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.
ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.
MEDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. C. E. Beevor: A Case of Chronic Spasms of the Upper Limbs.—Dr. Burney Yeo: On some Points in the Etiology of Phthisis.

Tuesday, March 24.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at the same hour. Ophthalmic Operations on Mondays at 1.30 and Thursdays at 2 P.M.
ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.
WESTMINSTER HOSPITAL.—Operations, 2 P.M.
WEST LONDON HOSPITAL.—Operations, 2.30 P.M.
ROYAL INSTITUTION.—3 P.M. Prof. Gamgee: Digestion and Nutrition.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 P.M. Sir Andrew Clark: Lumleian Lecture on some Points in the Natural History of Dry Pleurisies.
ANTHROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND.—8 P.M. Mr. A. J. Duffield: The Inhabitants of New Ireland and its Archipelago.—Mr. R. Brudenell Carter and Mr. C. Roberts: On Methods of Testing the Sight of Civilised and Savage Peoples.
ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—8.30 P.M. Discussion on Cholera, introduced by a paper from the President (Dr. George Johnson). Microscopical Specimens will be on view at 8 P.M.

Wednesday, March 25.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.
MIDDLESEX HOSPITAL.—Operations, 1 P.M.
ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.—Ophthalmic Operations on Tuesdays and Thursdays at 1.30 P.M.
ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Skin Department: 9.30 A.M., on Tuesdays and Fridays.
ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.
LONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.
GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.
UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Saturday, 2 P.M. Skin Department: 1.45 P.M.; Saturday, 9.15 A.M.
ROYAL FREE HOSPITAL.—Operations, 2 P.M.
KING'S COLLEGE HOSPITAL.—Operations, 3 to 4 P.M.
HUNTERIAN SOCIETY.—8 P.M. Mr. Jonathan Hutchinson: Notes on Symptoms.—Dr. Stephen Mackenzie will exhibit the Bacillus of Leprosy.
BRITISH GYNÆCOLOGICAL SOCIETY.—8.30 P.M. Specimens by Dr. R. Barnes, Dr. Edis, Mr. Reeves, and others.—Dr. Bell (Glasgow): Dysmenorrhœa.—Dr. Lamprey: Plural Monstrosities.

Thursday, March 26.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M.
ST. BARTHOLOMEW'S HOSPITAL.—Surgical Consultations, 1.30 P.M.
CHARING-CROSS HOSPITAL.—Operations, 2 P.M.
CANCER HOSPITAL, BROMPTON.—Operations, 2.30 P.M.; Saturday, 2.30 P.M.
NORTH-WEST LONDON HOSPITAL.—Operations, 2.30 P.M.
ROYAL INSTITUTION.—3 P.M. Prof. Dewar: The New Chemistry.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 P.M. Sir Andrew Clark: Lumleian Lecture on some Points in the Natural History of Dry Pleurisies.

Friday, March 27.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1.30 P.M.
ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.
KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.
CLINICAL SOCIETY OF LONDON.—8.30 P.M. Mr. Mayo Robson (Leeds): A series of cases of Spina Bifida treated by Plastic Operation (two patients will be exhibited).—Mr. Barwell: Three cases of Pistol-shot Wounds.—Dr. Hadden: A case of Choreiform Movements supervening in Infancy, and probably of Congenital Origin.—Mr. J. R. Lunn: Calculus and Tumour of the Bladder; lithotomy; death on the ninth day.
ROYAL INSTITUTION.—9 P.M. Prof. Victor Horsley: The Motor Centres of the Brain and the Mechanism of the Will.

Saturday, March 28.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.
ROYAL FREE HOSPITAL.—Operations, 2 P.M.
ROYAL INSTITUTION.—3 P.M. Mr. C. Armbruster: Richard Wagner.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.
All communications relating to the editorial business of the journal must be addressed "To the Editor."
Lectures, original articles, and reports should be written on one side only of the paper.
Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.
We cannot prescribe, or recommend practitioners.
Local papers containing reports or news-paragraphs should be marked.
Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

GAS FURNACE FOR DENTAL PURPOSES.

IN reference to a criticism by Mr. T. Fletcher of a paper by Dr. Rollins on Enamel Fillings, which recently appeared in the *Boston Medical and Surgical Journal*, it is but fair to the latter gentleman to state that early in 1880 we received from him a paper which not only contained a full description of a gas furnace for taking dental porcelains and artificial teeth, but was also accompanied by a woodcut of the furnace, taken from a photograph.

Quæsitor.—It is quite in the power of the guardians to continue the services of their medical officer, though living out of the district, in preference to the singly qualified practitioner living within the district; but in cases where great inconvenience is experienced by the poor from non-residence of their medical officer, representations having been made to that effect, the Local Government Board have acceded to the wishes of the guardians in sanctioning the appointment of a singly qualified medical man.

Dr. Kinkead (Galway).—The paper will be published in an early number.

HYDROCHLORATE OF COCAINE.

To the Editor of THE LANCET.

SIR,—I am at a loss to understand Mr. Churchyard's statement that when cocaine solution becomes old and flocculent he filters it through animal charcoal, adds salicylic acid, and it is as effectual as when freshly prepared. In a paper read at the Royal Institution here last week, I directed special attention to the fact that a solution of cocaine hydrochlorate of any given strength was most active when neutral or slightly basic; that the same solution if rendered decidedly acid is less effectual; in fact, that an acid hydrochlorate of cocaine, although more soluble, is less active than a neutral salt. There is no reason why solutions of cocaine hydrochlorate used frequently in large institutions should not be freshly prepared every two or three days; it is the work of a few minutes. If, however, it is desired to preserve it for any length of time, the suggestion of Dr. Fenwick in your issue of Jan. 31st—viz., to make the solution with camphor water—is an effectual preventive, more simple and far better than the remedy suggested by Mr. Churchyard.

I am, Sir, yours faithfully,

Liverpool, March 16th, 1885. CHARLES SYMES.

Dr. F. De Havilland Hall will find the correction made in another column.

THE LARYNGOSCOPIC MIRROR.

To the Editor of THE LANCET.

SIR,—With regard to the letters in your last issue respecting the use of glycerine and saliva to prevent the breath condensing on the laryngoscopic mirror, I would venture to point out that two objects are attained by heating the mirror in the usual way. First, it prevents the breath becoming condensed on the mirror; secondly, and not less important, it obviates the difficulties arising from the introduction of a cold body into the pharynx—i.e., spasm. This latter object is not attained by either glycerine or saliva. I am, Sir, yours faithfully,

Old Burlington-street, W., March 16th, 1885. GEORGE STOKER.

Pharmaceutist had better write to the Secretary of the College, to have the statement authenticated.

CARBOLIC OIL A REMEDY AGAINST MOSQUITOES.

To the Editor of THE LANCET.

SIR,—The practice of anointing is very nearly obsolete, probably owing to its being unsuitable to this climate; but it occurs to me that anointing with carbolic oil might prove to be an effectual remedy against the torment of mosquitoes to our troops in Egypt.

I am, Sir, yours obediently,

Bistree, March 2nd, 1885. D. DE BERDT HOVELL.

NEW TEST FOR TEA.

IT has been asserted that the quality of tea may be approximately estimated by the weight of ash which it yields, the value of tea being inversely proportional to the ash. M. Nikatinski has lately, says *The Grocer*, made a series of experiments with the view of testing the truth of this assertion, and finds that the ash is a very fair index of the quality of the tea. Thus a good Shanghai tea gave 5·16 per cent. ash, a cheap green brick tea 6·87, and two Orenburg teas, which are known to be adulterated with rose leaves, and of which the price was 115*s.* and 48*s.* per cwt., yielded respectively 7·87 and 10·42 per cent. of ash.

Dr. Kennedy is referred to the paragraph at the commencement of our analytical notices (see THE LANCET, Jan. 17th, p. 114) for information as to the terms on which we undertake such investigations.

Beaver.—Yes, to both questions.

"HOW TO CARRY, UNAIDED, AN INSENSIBLE MAN."

To the Editor of THE LANCET.

SIR,—In answer to the letter of "R. N. R." on the above subject in your issue of the 14th inst., I should recommend him to acquaint the officers in the Soudan, &c., with the following method adopted by and taught to the firemen of the London Fire Brigade.

A small platform, some forty or fifty feet high, has been erected on the roof of one of the buildings in the drill-yard. One half of the men who are drilling go up to this platform, and prostrate themselves in all kinds of peculiar attitudes, some on their backs, some on their faces, some on their sides, and some curled up. The other half have to go up and fetch them down single-handed. The rescuing fireman first straightens out the seemingly lifeless body of his comrade, and rolls it over on to the face. Then, taking hold under each armpit, he raises the body on to his right knee, so that he can put his arm round the waist, and the arm of the insensible man round his own neck. Taking a firm hold, he suddenly straightens himself up, and walks away with his burden in an upright position, and the whole weight of the other's body, supported and hooked, as it were, by the arm. He has then to carry his comrade through the window as best he can, and shoot him down the escape. I am, Sir, yours faithfully,

Leeds, March 16th, 1885. FRANK SALTER, L.R.C.P., &c.

To the Editor of THE LANCET.

SIR,—Let "R. N. R." try the following methods: 1. Pig-a-back. 2. Weigh butter. 3. Fireman's lift. Methods 1 and 2 are both well known as children's games. For 1, spread the patient's legs, and sit him up; then kneel, or, better, crouch down between the legs with your back to him, draw his arms as forward as possible over each of your shoulders, and by stooping forwards lift him gradually up until you stand upright; a hoist or two while holding firmly to the arms will mend the position. In 2 the bearer should get the patient into a sitting posture, then kneeling or crouching himself, back to back, hook his arms into the patient's arms, and gradually raise himself and his load until he stands up. The best, however, is the third method, which is described in Captain Eyre Shaw's book on Fire Protection, p. 271. The patient by this method is so well sustained that a certain amount of freedom is permitted to the hands of the bearer, which could be utilised in carrying any portable article, for climbing a rock, descending a ladder, &c. I am, Sir, yours truly,

March 16th, 1885. G. C. S.

To the Editor of THE LANCET.

SIR,—In reply to the query of your correspondent, "R. N. R.," I beg to suggest as follows. First, if possible, drag the insensible man close to a tree, large stone, or any object which may assist you in raising him from the ground; then strap or tie the legs loosely together below the knees; next turn the patient on his right side, and lie down on your left side, with your back to the patient's stomach, and insert your head between his thighs or knees above the strap; turn as much as possible upon your stomach, bringing the body with you, and you will not find it difficult to rise, and by a few jerks the body can be brought into a position convenient for carrying. The advantages of carrying a body in this position are obvious—viz., the compression of the abdomen, the position of the head, and the legs balancing the body (with perhaps a rifle laid at the back of the knees), with respect to the patient, and to the bearer the freedom of the chest from compression, and of the right arm for self-defence, &c. I am, Sir, yours truly,

Romsey, March 17th, 1885. SPENCER H. SIMPSON.

X. X.—With ordinary prudence, we believe the pay to be quite sufficient to defray all necessary expenses. We have known many gentlemen who have found it to be so.

Practitioner.—The Vaccine Department, Local Government Board, Whitehall, S.W.

THE LUNACY AMENDMENT BILL.

To the Editor of THE LANCET.

SIR,—I hope the profession at large will, through their Parliamentary representatives, secure the right of every registered practitioner to sign lunacy certificates. The monopoly which the Bill proposes to create should be prevented. I am, Sir, yours truly,

Cashel, March 12th, 1885. T. LAFFAN.

DR. BOUGIER'S THESIS.

OUR Paris Correspondent writes:—"In re-reading Dr. Bougier's thesis, referred to in my letter of last week, I find that the word 'moss' is evidently incorrect; it should be *froth*. The latter part of Conclusion 1 should therefore read thus: 'The appearance of froth at the mouth would be of some diagnostic value.' In Conclusion 6: 'The characteristic froth is found only in the submerged.' In using the terms 'submersion' and 'immersion' I simply followed the author, who evidently meant to express the former as taking place during life, and the latter after death. For instance, in Conclusion 3 the author states that the epiglottis is vertical in the submerged; it is only half open in the corpses immerged. Again, in Conclusion 4 he makes the same application of the words, which, after all, may simply be a distinction without a difference."

R. B. M.—1. It is exceedingly improbable that the quantity of the mercurial preparation reported to have been taken would cause "all the symptoms of severe poisoning," unless some soluble salt of mercury was present as an impurity.—2. The dose was certainly somewhat large, considering its frequent repetition. We have often written against the practice of submitting to treatment by medicines without medical advice. If people will persist in ignoring this warning, they must abide by the consequences. A chemist is not under the same legal obligations as a qualified medical man; but, of course, he is liable to a penalty if he administers a poison.

Mr. Foley.—The description of the apparatus will be inserted on receipt of the block.

CASE OF MONSTROSITY.

To the Editor of THE LANCET.

SIR,—The following case possesses features which appear to me worthy of record.

A. T——, aged forty-two, married nineteen years, had ten children, the eldest eighteen years old. Menstruation ceased last March, and she expected her confinement about the middle of November, at which time she consulted a doctor, who told her that if she went much longer she would probably have twins, she replying that she did not care so long as they were not "Siamese." On Jan. 22nd she went to the lying-in hospital, and stated that she thought there was something wrong with her, and that hæmorrhage had previously occurred. On the 23rd I found the patient had been in labour since 10 P.M. the previous night. On examination the head was found pressing on the perineum, and all pains had ceased. This being the case, I immediately applied the forceps, and delivered the head without difficulty; but it was not until after prolonged traction that the shoulders partially emerged, when I discovered that there was an outgrowth from the chest which prevented any further movement in that direction. I therefore passed my hand round the lower part of the abdomen, and delivered the breech and legs. The child was now entirely born; but finding it connected from the neck to the umbilicus with another child still in the uterus, I laid hold of the legs of the second one, and delivered it without difficulty. The placenta followed in a few minutes. There was only one cord proceeding from an umbilicus common to both. The children were dead, and were both boys. In the ordinary position they faced one another; but the connecting link was sufficiently lax to allow them to lie partially side by side. In every other respect they were perfectly formed, and weighed 11 lb. The next day, when the mother heard of their condition, she told the nurse that in March last she went to see the "Two-headed Nightingale," and fainted at the sight. I regret to say that the occurrence so affected her that three days after she committed suicide by jumping out of a window.—I am, Sir, yours obediently,

Birkenhead, March 9th, 1885. B. R. JOHNSTON, M.R.C.S., &c.

THE GENERAL HOSPITAL, BIRMINGHAM.

To avoid possible inconvenience, we may call attention to a printer's error in an advertisement inserted in our last issue announcing the appointment in April next of a Resident Medical Officer to the above hospital. The error consisted in stating the salary to be £150, instead of £130, with board, &c.

A Country Doctor (Perthshire) should in the first place remonstrate—best by personal interview—with the medical practitioners of whose conduct he complains.

Aphide.—We do not prescribe.

Mr. Fletcher (Ormskirk).—The reply referred to was addressed to another correspondent.

"CONSTANT TINCTURES."

To the Editor of THE LANCET.

SIR,—In reply to "E. W.," we beg to state that the constant tinctures" are made, not only from "good sound drugs," but from "picked" good sound drugs, and yet it is necessary to standardise them. His statement that he has rarely found any appreciable difference in the specific gravity of his more active tinctures is no answer to the fact, generally accepted by those who have worked on the subject, that tinctures prepared as he describes will vary in alkaloidal strength. There is no direct relation between the specific gravity of a tincture and its alkaloidal value. We remain, Sir, yours faithfully,

Oxford-street, March 18th, 1885. SQUIRE AND SONS.

DR. WRIGHT'S SANITARY NIGHT-LIGHTS.

MESSRS. J. C. & J. FIELD, of Lambeth, have forwarded us a sample of these useful adjuncts to the sick-room. These night-lights diffuse eucalyptol throughout the apartment, and their use is one of the most simple and effective methods of rendering rooms in which they are burnt wholesome and fresh. To some, however, the powerful smell of eucalyptol which pervades the apartment in which one of these night-lights has been burnt may be objectionable; but to persons to whom this odour is not an annoyance we can recommend them.

Mr. F. Dillon Woon.—The intention of the writer was to say that probably something like 90 per cent. of persons exposed to small-pox would take the disease. There are undoubtedly different degrees of vaccinating ability, as of every other kind of ability. One thing is clear, that there never was so much attention paid to the attainment of good vaccination as now.

L. M.—We will endeavour to find space for the notes in an early number.

"ON SYNCOPE, AND A METHOD OF AVERTING IT."

To the Editor of THE LANCET.

SIR,—In justice to myself, will you permit me to point out, with reference to Dr. Notley's article in your last issue on the above subject, that I have for some considerable time past adopted the hot water application to the head, which I have hitherto looked upon as a novel method introduced by myself in resuscitating patients when in a state of collapse other than that due to the administration of anæsthetics. I have pursued this method in a variety of instances, and have on several occasions alluded to the fact. For instance, in THE LANCET of Dec. 13th, 1884, under the heading of Anæsthetics, I make use of the following sentence, after describing the mode of application of almost scalding water to the forehead by means of a flannel:—"I have invariably found the 'hot water' application to be invaluable in various cases of syncope, and above all for the most speedy restoration or establishment of the circulation of new-born infants."

I am, Sir, yours truly,

Baron's Court, S.W., March 11th, 1885. R. FITZROY BENHAM.

THE report of the last meeting of the Ophthalmological Society, and several articles and communications, are unavoidably held over till next week.

ERRATA.—In Dr. Lucas's letter on Cascara Sagrada, published in our last issue, the word "pathological" was misprinted for *physiological* in the second line.—In our annotation columns last week, regarding the appointment of Dr. Simpson to the Surgeon-Generalship, the word "Bombay" was misprinted for *Bengal*, that gentleman being appointed to be Surgeon-General of the Presidency of Bengal, and not that of Bombay.

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Dr. Braxton Hicks, London; Professor Humphry, Cambridge; Dr. De Havilland Hall, London; Dr. Hermann Weber, London; Dr. Wickham Legg, London; Mr. W. J. C. Miller, London; Dr. Pye-Smith, London; Dr. Leech, Manchester; Mr. S. J. Sulemani, Bombay; Mr. J. J. Joseph, London; Dr. Barnes, London; Dr. Ogier Ward; Mr. Eades, London; Mr. H. E. NOTICE.—Advertisers are requested to observe that it is contrary to the Postal Regulations to receive at Post-offices letters addressed to initials only.

An original and novel feature of "THE LANCET General Advertiser" is a special Index to Advertisements on page 2, which not only affords a ready means of finding any notice, but is in itself an *additional* advertisement.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Answers are now received at this Office, by special arrangement, to Advertisements appearing in THE LANCET.

Terms for Serial Insertions may be obtained of the Publisher, to whom all letters relating to Advertisements or Subscriptions should be addressed.

Advertisements are now received at all Messrs. W. H. Smith and Son's Railway Bookstalls throughout the United Kingdom, and all other Advertising Agents.

Tables of Contents, with the Index of Advertisements, for each Number can be had on application to the Publisher.

Agent for the Advertising Department in France—J. ASTIER, 66, Rue Caumartin, Paris.

Lumleian Lectures

ON

SOME POINTS IN THE NATURAL HISTORY OF PRIMITIVE DRY PLEURISIES.

Delivered before the Royal College of Physicians,

BY SIR ANDREW CLARK, BART., M.D.,
FELLOW OF THE COLLEGE.

LECTURE I.

MR. PRESIDENT AND GENTLEMEN,—I purpose in this and the following lectures to consider some points in the natural history of primitive dry pleurisies. Upon secondary pleurisies, upon pleurisies provoked by pneumonia, pyæmic blocks, tubercle and neoplasms of every sort, it is not at present my intention to dwell. By a dry pleurisy I mean such an inflammation of the pleura as issues in an exudation of lymph into the substance and upon the surface of the membrane unaccompanied by an amount of serous effusion sufficient to yield physical signs conclusive of its presence. Entering upon this inquiry, we are met by the question, Do such pleurisies exist? and on the side of affirmation, as well as on the side of denial, are ranged some of the highest authorities in medicine. Even when it has been admitted by the weight of evidence that dry pleurisies are pathological as well as clinical entities, their influence in originating secondary disease of the lung has been hotly contested. From the days of Laennec until now the most opposite opinions upon this subject have been advanced; and whilst one leader has declared primitive dry pleurisies to be mere clinical curiosities, another has asserted that they invade the lung and produce secondary and serious changes therein. The study of this controversy is at once sad and edifying; for whilst it shows us, even in the highest order of minds, how difficult it is, in the search for knowledge, to be in the philosophic sense impersonal, it makes plain to us the puerility as well as the peril of dogmatism and of finality in scientific statements. The scope of my inquiry is narrow, and the results of it are but few and imperfect. Nevertheless, I indulge the hope that they will not be found entirely useless, since, whatever may be thought of the inferences drawn from the cases forming the subject of this inquiry, the cases themselves will remain for future study; and, touching one of the most important questions of the age in which we live, may excite to fresh investigation others more qualified than I am to pursue it with profit. Furthermore, it will be to many disappointing to find that the direction of my inquiry will make it more interesting to the student of clinical medicine than to the student of pathological histology. But herein may lie the justification of my small endeavours; for whilst I remember that the traditions of this College make it sacred to the advancement of knowledge for its own sake, I cannot forget that they make it also sacred to the forcing of that knowledge into fruit for the uses of man.

In the present lecture I shall set forth the grounds which have led to the institution of this inquiry. In the second lecture I shall consider the anatomical constitution of dry pleurisies, their varieties, the changes which they undergo, and the influence which they exert on the evolution of pathological changes in the lung. In the third and last lecture I shall relate, in as far as they are known to me, the clinical peculiarities of the chief affections of the lung originating from dry pleurisies, and I shall conclude with a series of propositions which appear to be justified by the facts collected in the course of this inquiry.

In proceeding to set forth the grounds of this investigation, I find myself embarrassed by the number and variety of materials at my command. A critical examination, however, soon makes it plain that they fall naturally into groups, that the groups may be arranged in the order of an increasing complexity and importance, and that a single instance selected from each group will fairly represent the whole. Now, the grounds of this inquiry are, in the first instance, cases, and I have collected and related them in abstract with as much care as I could command. Nevertheless, they are all of them in varying degrees incomplete, and in some few particulars they may be even inaccurate. For a literal and sustained accuracy in narration is one of the rarest gifts granted to men; and the difficulties encountered in relating a case, and in recording its progress with minuteness and exactitude over a period of years, are so great that I cannot understand how, unless exceptionally, they are so commonly and easily overcome. Furthermore, after long study of a case, the sum of our knowledge of it comes to be made up partly of bare facts capable of literal record, partly of complex facts into the account of which our own subjectivity more or less largely enters, and partly of subjective impressions which, if they do not actually combine with the naked facts, so colour them that sometimes they are practically transfigured. I recognise this peril, from which I suspect no one is wholly privileged; and I have endeavoured in the narration of my cases to purge them of subjective adulterations, and to present them in their baldest objective forms. But to say that I have been entirely successful, would be to assume that I am more than entirely human. Lastly, the cases are not related in chronological order; but they are related in such order as seems best calculated to set forth the progress of primitive dry pleurisies, and the ways in which they invade, alter, and destroy the lungs.

CASE 1.—In 1866 I was consulted by a gentleman, thirty-five years of age, married, a traveller, and of somewhat irregular habits. He was fair and moderately nourished, but looked pale and ill. His family history was good; and of his personal history he said that he remembered having suffered from no special complaint, but that latterly he had been often ailing and sometimes "rheumatic." He consulted me on account of an odd feeling which he had in his left side, and described it as "resembling the movement of something out of joint." On examination, I found a grating pleural friction round the whole base of the left lung; but neither in the upper part of that lung, nor in any part of the right lung, could other indications of disease be discovered. Except in the region of pleural friction the breath sounds, the vocal resonance, and the percussion were normal. There was neither cough nor expectoration, but deep breathing produced general discomfort in the left side; there was no constitutional disturbance; and, beyond a slight gastro-hepatic catarrh, no signs of disorder elsewhere. Two months later the pleural friction had extended to the whole lower half of the left lung, but no material change had occurred in the local or general condition of the patient. Twelve months after the first examination the patient had failed in general health and suffered from a little cough, mucoid expectoration, and breathlessness on exertion. Pleural friction and creaking were heard at places throughout the lower third of the left lung. A superficial crackling or crepitation could be evoked by deep breathing or coughing; vocal resonance was diminished; there was dulness on percussion, and the tactile vocal fremitus was feeble. The lower part of the side appeared to be slightly contracted; the cardiac impulse was visible under the left nipple; the right ventricle was slightly dilated; the pulse was 76; the temperature was normal; and there was no evening fever. I did not see this case again; but a year afterwards I heard that he had been for a few months insane; that his chest had given no signs of trouble, and that he had just emigrated to New Zealand.

CASE 2.[1]—In February, 1874, Mr. Hutchinson requested me to examine, in his wards, a man who had somewhat suddenly developed pulmonary symptoms of an obscure kind. The patient was thirty-four years of age, tall, well built, and well nourished. He complained merely of urgent dyspnœa. His face was dusky and expressive of great anxiety. He breathed with great difficulty and labour; the thorax appeared to be inflated and incapable of complete recoil on expiration; the veins of the neck were distended; the skin was of a bluish tint; and the extremities were cold and damp. Examination of the chest yielded few definite results. There was nowhere dulness on percussion or any recognisable change in the tactile vocal fremitus. Everywhere the breath sounds were loud, harsh blowing, and here and there accompanied by a fine and moist or a rustling and dry crepitation. Throughout the axillary region of the right side and over the lower two-thirds of the back there was heard a superficial moist crackle or large crepitation, sometimes replaced by friction. Like sounds were heard in disseminated circumscribed patches in corresponding regions of the opposite

[1] See Appendix, Note 1.

side. The action of the heart was rapid and irregular; epigastric pulsation was strongly marked; the pulse was small and running; the temperature was under 100°. The tongue was swollen, furred, and bluish; the abdomen was distended; the bowels were confined; the scanty urine was loaded with purple lithates and free from albumen. The patient was restless, had slept little, and was occasionally delirious. On the day following my examination he died. After death both lungs were found to be emphysematous. The greater part of the right pulmonary pleura was coated with a thickish layer of loose, soft, reticularly arranged lymph more or less adherent to the subjacent membrane, and containing in its meshes a turbid, yellowish, glutinous fluid. Both the lymph and the subpleural areolar tissue were studded with small extravasations of blood. In the lung immediately beneath the pleura were narrow, irregular, and interrupted tracts of pneumonic consolidation. Similar appearances to a much less extent were found on the pleura and in the lung of the opposite side. The heart was dilated and somewhat soft. The valves and their corresponding orifices were free. In a few of the smallest branches of the pulmonary artery plugs were found.

CASE 3.—In January, 1873, Dr. Stephen Mackenzie called my attention to a patient in Harrison Ward of the London Hospital. He was about thirty years of age, tall, florid, thin, and healthy looking. He had been admitted for bronchitis and gastric catarrh. As the bronchial attack subsided and its attendant râles disappeared, there was noticed all over the right side a very superficial crackling and crepitation. It was just recognisable by the hand placed lightly over the side; it was little influenced by deep breathing or by coughing; and when listening with the stethoscope the impression made upon the mind was that the crackling was produced either in the walls of the chest or in the parts immediately subjacent. After a few weeks the patient was discharged from the hospital at his own request. He was in all respects well, except that the superficial crackling and crepitation remained unaltered. A year afterwards this patient was readmitted into the hospital. I did not myself see him on that occasion, but I was told that he had had a slight bronchial attack; that after its subsidence the right lung was found in the same state as before, and that the left lung was unaffected. In 1876 I had an opportunity of re-examining the patient. Except for a slight cough, mucous expectoration, and shortness of breath on exertion, he was fairly well, and able to follow his work. The left lung was quite free from any signs of disease. The right side moved less freely in breathing, looked slightly flattened and contracted, and the cardiac impulse was near the sternum below the cartilage of the fourth rib. Over the lower third from the front of the axillary region to the spine there were marked dulness, diminution of tactile vocal fremitus, feeble breath sounds, and impaired vocal resonance. During forced inspiration, practised after coughing, there could be heard in places creaking or obscure friction and some deeper sounding coarse moist crepitation. There was no notable change in the condition of the heart. The pulse was under 80. The temperature was slightly subnormal.

CASE 4.—In June, 1875, I was consulted by a young man for cough, expectoration, and pain in the right side. He was eighteen years of age, tall, and moderately nourished. The family history was good. Fourteen months before his visits he contracted a right pleurisy, and since then his chest had not been well. Nothing abnormal was discovered in the digestive, circulatory, genito-urinary, or nervous systems. On examining the chest, it was found that the cardiac impulse fell between the fifth and sixth ribs two inches in front of the nipple. The heart's action was strong and regular; the pulse was 68. The temperature was normal. The left side was normal in form and movement. The right side was slightly flattened, moved less freely on inspiration, and, except at the upper fourth, was dull on percussion. The tactile vocal fremitus was unaltered. Auscultation revealed in the dull region superficial creaking leather sounds, bronchial breathing, increase vocal resonance, superficial clicking, and large moist crepitation. This patient went to South Africa. I saw him two years afterwards on his return to England, and he declared himself to be quite well. A careful examination brought to light no evidence of disease except in the right side of the thorax, which was flattened, contracted, and a little twisted. The corresponding shoulder was depressed, whilst the lower angle of the scapula projected outwards from the ribs. Over the lower four-fifths of the right lung there was complete dulness on percussion, diminished tactile vocal fremitus, feeble breath sounds, no râles, and much impaired vocal resonance. During forced inspiration, creaking and sometimes little grating sounds were heard. I have not seen the patient again.[2]

CASE 5.—This was the case of an unmarried American gentleman, fifty-two years of age, a patient of Prof. Pepper of Philadelphia, who had recommended him to go to England for the benefit of change. He complained of general ill-health, of a nearly dry teasing cough, of shortness of breath, weakness, and indigestion. He was pale, thin, anxious-looking, depressed, and supposed to have had syphilis at a date not recorded. The illness for which I was consulted began in 1877, with an obstinate and incoercible right dry pleurisy. He went to Colorado, Florida, and the Sandwich Islands, with no resulting benefit. Subsequently he visited Toronto, and there began to improve. At the time of examination the patient was suffering from gastric catarrh, and had a suspicious-looking ragged ulcer, about the size of a sixpence, on the posterior wall of the rectum, within an inch of the anus. The urine was of fair density, and slightly albuminous. The heart was beating feebly a little to the right of its normal situation; there were no murmurs; the pulse was 84, small and compressible; temperature normal. The left lung on examination yielded no signs of disease. The right side of the thorax was a little flattened, and on inspiration moved much less freely than the left. Over the lower two-thirds, and chiefly from the anterior border of the axillary region to the spine, there were almost complete dulness on percussion, diminished tactile vocal fremitus, feeble and irregular breath sounds, slightly increased vocal resonance, and no râles. Deep forcible inspirations brought out superficial rustling crepitation, creaking leather sounds, and at one or two parts grating friction. Patient complained of general pains which disturbed his sleep, and of stiffness and achings of the joints. Nine months afterwards I re-examined the patient. His general health was much improved, but the condition of the right lung was unaltered, and there was still a trace of albumen in the urine.

CASE 6.—For this case I am indebted to the kindness of Dr. Goodhart. Unfortunately no dates are given in the record. Nine years before death the patient was admitted into Guy's Hospital for chronic interstitial nephritis. Soon afterwards he had an attack of right dry pleurisy, followed by hæmaturia. Four years, and again two years, before death the patient had hæmoptysis. The physical signs were reported to be those of bronchitis and of phthisis. The patient died unexpectedly and suddenly, with signs of failing action of the kidneys. On inspection after death it was found that the right lung was surrounded by a greatly thickened pleura, at some parts a third of an inch in thickness; that the whole upper lobe was converted into a mass of fibroid tissue, traversed by slightly dilated bronchial tubes; and that it seemed as if the fibroid invasion had arisen in and extended from the inflamed pleura. Part of the lower lobe was simply collapsed and penetrated by tracts or bands of fibroid tissue, which, starting from the pleura, were lost in the lung. A similar, but less advanced condition, existed in the summit of the left lung. The heart weighed eleven and a half ounces; two of the aortic valves had fused into one, and the third was enlarged. The kidneys were slightly granular on the surface, but there was no marked cortical wasting. There were, however, some recent epithelial changes and intertubular congestion.

CASE 7.—This case occurred in a gentleman seventy-six years of age, whose family was reported to be free from any taint of phthisis. Summoned in 1870 to see him on account of a small recurring hæmoptysis, I was informed that at about eighteen he had had a right pleurisy which "persisted in a curious way" for many months; that almost ever since that time he had suffered from his chest; that he had had several attacks of hæmoptysis; that he was liable to frequent and severe colds; and that notwithstanding these facts his general health had been fairly good, and he had been between his attacks equal to the ordinary duties and enjoyments of life. The attack of hæmoptysis having ceased in a few days, I was able to examine the chest with some care. The heart was found to be beating against the cartilage of the third rib on the right side. This was flattened and irregularly retracted; the shoulder was depressed; the scapula at its lower part projected outwards from the ribs; the neck was swollen and its superficial veins were distended and

[2] See Appendix, Note 2.

tortuous; and here, as well as in the face, the skin was of a pale dull leaden hue. The whole side, front and back, except at the apex, was dull on percussion, the tactile vocal fremitus was rather increased; the breath sounds were of the hollow bronchial variety, loud, harsh, and blowing; there was no vesicular breathing, but instead of it there were large, moist, gurgling rhonchi; and the vocal resonance along the course of the bronchial tubes was bronchophonic and almost pectoriloquous. At the base of the lung the physical signs were of a similar character, but much less advanced. Over the summit of the lung the tactile vocal resonance was diminished; the breath sounds, though feeble and harsh, were of the normal type; and the vocal resonance, except at the inner end of the clavicle, was diminished. The percussion note over the summit of the lung was of a tubular character, and resembled the sound which, in children, one can elicit by tapping the upper part of a lung, the lower part of which is surrounded by fluid. The left side was enlarged, rounded, and moved fully and freely on inspiration. Tactile vocal fremitus was everywhere distinct; the percussion note was more than naturally clear and resonant; the breath sounds, the vocal resonance, the respiratory rhythm, and the pleural movements were everywhere normal. Six weeks after the first I made a second examination of the patient when he had returned to his normal state. I found that he suffered from a slight catarrhal dyspepsia; that the urine, of low density, contained always a little albumen; that he had a habitual slight cough with muco-purulent expectoration; that when he was struck with a severe bronchial attack the cough became paroxysmal and ended in vomiting; and that he suffered from time to time with pains about the right shoulder and side. During this examination I heard but few râles; but a creaking leather sound—a sound as of the creaking of a new saddle—was clearly audible during deep inspiration. I did not again see this gentleman, who subsequently died of bronchitis, under the care of Messrs. Huxley and Nankivell at Torquay. Since these notes were written I have learned from Dr. Toogood many interesting particulars of this patient's case. Chief among them is the circumstance that the patient suffered occasionally from attacks of dry pleurisy on the right side.

CASE 8.—In the early part of 1870 I was summoned to see a gentleman complaining of pain in the lower part of the left side, which he considered to be an attack of internal gout. The patient was sixty years of age, tall, thin, and somewhat infirm, but vivacious. He had suffered from regular attacks of gout for many years, until the last five years, when the attacks became irregular, and when, as the patient alleged, instead of occurring in the foot or hand, they occurred in the lower or back part of the left side. On examining the chest, I found slight dulness over the lower and back part of the left side, increased tactile vocal fremitus, harsh grating friction, feeble breath sounds, and slightly modified vocal resonance. The patient was himself conscious of the pleural friction, and it could be felt by the hand laid lightly on the chest. Nothing abnormal was discovered in the right lung. There were uneasiness in the left side and shoulder, pain and slight cough on deep inspiration, some slight difficulty of breathing on exertion, and a little viscid, frothy expectoration discharged with difficulty. The heart was large, weak, irregular, and murmurish in the mitral area; the arteries were slightly thick. The patient suffered a good deal from indigestion. The bowels were sluggish. The urine had a density of 1018, frequently deposited showers of uric acid, and contained traces of albumen. There were no signs of disease in the nervous system. The skin was for the most part harsh and dry, but now and then there were partial sweatings. The hands and feet were deformed by repeated attacks of gout. The patient was a generous liver, and dined almost daily *à la mode* in the company of his friends. The patient continued in much the same condition until June, when he went to the south of England, and I lost sight of him for two years. During his absence it was said that his chest was quite well, but that he had had repeated attacks of ordinary gout. Towards the close of 1872 I was again summoned to see this gentleman in London, and I found him in every way worse. He had frequent paroxysms of cough, ending partly by cough, partly by vomiting in the expectoration of a fetid muco-purulent matter often stained with blood; he was breathless on exertion, and he had pain, aggravated by coughing, round the base of the right lung. The sputum contained areolæ of elastic tissue, and made sure the diagnosis of an excavation in the lung. The whole base of the left lung was now completely dull on percussion, the tactile vocal fremitus was diminished, and, except at one point about to be noticed, the breath sounds were feeble and the vocal resonance diminished. At the point excepted in the middle of the posterior base, and a little way above the upper limit of hepatic dulness, the breath sounds were cavernous and the voice bronchophonic. Occasionally either no cavernous breathing was heard in this locality, or else there were bubbling or gurgling râles. Immediately after free expectoration the breath sounds were hollow; some hours afterwards, and before the occurrence of a paroxysm of coughing, auscultation gave no evidence of the presence of a cavity. The right lung was entirely free from any sign of disease. The heart, drawn a little upwards, was weak, irregular, and indistinctly felt. The pulse, frequent and quick, beat over a hundred times a minute. There was not only no elevation of temperature, but the temperature, unless on exceptional occasions, varied from one to two and a half degrees below the standard of health. The digestion was much disturbed, the bowels were obstinately confined, and the patient was troubled with hæmorrhoids. The urine was now abundant and pale; it contained habitually traces of albumen, but there were no casts. The patient was thin, weak, ailing. The face and particularly the eyelids were puffy. The finger ends were swollen. The superficial cervical veins were distended. The skin was yellowish and dry. There had been no serious attack of external gout for many months. The nervous system was unstrung and the temper had become irritable. The nights were restless and vaso-motor storms were frequent. On this occasion I saw the patient only twice or thrice. He did not improve much, and thinking that he needed more frequent relays of food and more ample supplies of wine than my regulations for management permitted, he sought the advice of another physician who understood his constitution better than I, and who held more liberal views respecting its management. In 1875 the patient again came under my care. He was thin, weak, and worn; his feet and legs were œdematous; he was depressed in spirts and irritable in temper; his nights were sleepless and his days distressed by frequent paroxysms of exhausting cough. The expectoration was abundant, muco-purulent, and sometimes almost unbearably fetid. On occasions the fetor disappeared for days and the expectoration consisted only of a frothy viscid or watery mucus, dotted with tiny pellets of pus or of blood. His breathing, always short and shallow, turned into distressing breathlessness when he ascended a flight of stairs. The digestive organs were greatly disordered, flatulent attacks with palpitations were frequent, the bowels were irregular, and the urine, having a density of 1012, contained about 5 per cent. of albumen but no casts. The skin, harsh and dry, had a pale-bluish or leaden tint. The eyelids were œdematous and the right side of the neck and chest as well as the right upper arm were traversed by gorged and tortuous veins. The heart, drawn upwards and outwards, lay behind the third rib, its action was weak and irregular, and, in addition to a low-pitched murmur in the mitral area, there was a loud roaring systolic bruit close to the cartilage of the third rib at its junction with the sternum, and thence along the course of the aorta. About this time Mr. G. W. Mackenzie was associated with me in the charge of the case, and to his skill, judgment, and firmness was due the improvement which subsequently occurred in the patient's condition. By careful management, chiefly hygienic, the patient improved greatly in general health; but the signs of local lung disease, although quiet, persisted. Returning to the duties and pleasures of society and continuing therein, the patient in autumn caught a severe cold. This was followed by small attacks of generalised gout, an increase of albumen in the urine, œdema of both lower extremities and failure of general health. Again, after a time the general condition of the patient improved; but as the bronchial catarrh persisted, and as there were evidences in the sputum of advancing lung disease, the patient was sent to Torquay, and placed under the care of Dr. Usher Huxley. There for some months the condition of the patient's chest improved; and with the exception of daily paroxysms of cough ending in vomiting, habitual but scarcely felt breathlessness, and occasional attacks of irregular and tumultuous action of the heart, the patient suffered little and enjoyed his limited life. On a certain day, however, he having got chilled, he began to have irregular accessions of fever. The appetite failed,

the albumen in the urine increased, a pleuritic effusion appeared in the right side, the breathing became oppressed, the heart slowly failed, and the patient, falling into a state of stupor, died. To Dr. Usher Huxley I am indebted for an account of the autopsy, and for that part of the affected lung which included the naked-eye evidences of disease. The base of the left lung was surrounded by several layers of adventitious pleural membranes, varying in consistence and character. The innermost of these layers appeared to extend through the interlobular fissures, and along the bloodvessels into the substance of the lungs, which was hard, tough, dark, and cut with difficulty. Within an inch of the posterior surface of the lung, and near its base, were two irregular cavities, containing blood-stained purulent matter. The walls of both cavities were shaggy, and in the immediate neighbourhood of one of them were a few small knots of fibroid tissue, about the size of hemp-seed. There were no bronchial dilatations. The bloodvessels were everywhere thickened. The lymphatics of the interlobular fissures were here and there swollen, knotted or saccular, and contained at some parts small clots, and at others masses of a cheesy consistence and aspect. The upper part of the lung contained no deposits of any kind. The free margins and isolated central portions of the lung were emphysematous. The pleura investing the summit was much thickened. Except for patches of pleural thickening, the right lung was apparently unaffected by disease. The heart was dilated and soft; the valves were roughened; and the aorta was atheromatous and slightly dilated. The kidneys were congested, the capsules adherent, and the cortex granular. Nothing of the nature of tubercle as ordinarily understood was anywhere found.

CASE 9.—In 1866 a man was admitted into the London Hospital, and placed under my care, complaining of severe pain in the lower part of the right side, passing upwards as high as the nipple and downwards as far as the umbilicus. He was twenty-three years of age, tall, dark, thin, and by occupation a costermonger. There was no family history of phthisis, and the patient himself had enjoyed good health until the appearance of the illness for which he had been admitted. He confessed, however, to the habitual and free use of alcoholic beverages. A week before admission the patient had a rigor, followed by severe pain in the right side, cough, fever, and considerable prostration. The whole facts of this case were carefully studied and recorded by my colleague, then my clinical clerk, Mr. J. M'Carthy. From his notes I have extracted all that seemed to bear directly upon my present purpose. The patient complained of dry cough, of pain in the right side, made excruciating by coughing or by deep inspiration, of loss of appetite, and of great prostration. The lower part of the right side moved imperfectly on inspiration. The tactile vocal fremitus was slightly diminished. There was no marked dulness on percussion. Over the whole base could be heard with the stethoscope pleural friction, superficial moist crackling, and, at scattered circumscribed places, bronchial breathing with increased vocal resonance. Between those places the respiratory sounds were rather feebly heard through the crackling and friction. Examination of the upper part of the lung yielded no signs of disease beyond a few mucous râles. The left lung was apparently healthy. The heart's action, unaccompanied by any abnormal sound, was frequent and weak. The pulse 110, small and compressible. The temperature 103°. The tongue was loaded; the bowels were confined; the urine was scanty, and deposited purple lithates. The patient looked and felt very ill. After a week he had frequent distressing cough with muco-purulent expectoration, and occasional attacks of dyspnœa, with severe pain in the right side. The physical signs remained practically unaltered. Fever continued, and the patient took little food, had restless nights, and was extremely prostrate. At the end of a month he was much worse. The physical signs, still of the same general character, had extended to the whole lower third of the right side, and there was extreme tenderness over the hepatic region. Coarse, moist crepitation, with mucous râles, was heard throughout both lungs. There were harassing cough, thin muco-purulent expectoration, and occasional attacks of breathlessness in the midst of shallow and painful respirations. The pulse was 120; the temperature at night 104°; there were occasional chills during the day, and sometimes profuse sweats at night. The patient lay upon his back, took little food, and expressed himself as very ill. The tongue was loaded and the breath fetid. Constipation alternated with diarrhœa, and light with dark fæces. The urine, more abundant in quantity, contained a little albumen. Exploration of the right side with a fine trocar showed that there was no free fluid in the pleural sac. Several physicians who at this time examined the case suspected it to be one of acute tuberculosis, with secondary pleuro-pneumonia of the base of the right lung. Before the patient's death, about two months after admission, new physical signs arose in the base of the right lung, two inches below the nipple. Over a circumscribed space, dull on percussion, there were heard cavernous breathing, pectoriloquy, and on coughing a hollow gurgling rhonchus. After death it was found that the structural evidences of disease were confined almost entirely to the lower third of the right lung and the upper surface of the liver. The base of the lung was surrounded by a thick layer of loose, yellowish, soft, and almost diffluent lymph, infiltrated at parts by a fluid resembling pus, but composed of degenerating cells of various forms, with glandular débris. The old membranous exudations in contact with the pleura were quite firm, and could be traced throughout the lower part of the lung in two forms: as white, tough, intersecting bands, and as a dense, hard, almost formless fibroid infiltration. At the lower part of the base, near the anterior surface, there were found pyriform bronchial dilatation and one or two minute cavities. Throughout the intercurrent portions of lung two different structural changes were visible. The first consisted of disseminated, rounded caseous lumps, for the most part confined within the limits of the pulmonary lobules, but sometimes extending beyond them. Histologically the lumps resembled the consolidations begotten in caseous pneumonia, and were at one or two points melting into excavations. The second kind of structural change was due to the presence, in small numbers, of spheroidal greyish or yellowish bodies, about the size of hemp-seed and resembling tubercles. They had not, however, the arrangement of parts and structural characters of veritable tubercle. They were divisible into two groups; the members of one group were mere knots of fibroid tissue; the members of the other appeared to consist of choked and distended lymphatic spaces, traversed by an adenoid reticulum. In the abundant soft lymph lying between the under surface of the lung and the diaphragm there was found an abscess about the size of a large walnut, and this abscess could be followed through the diaphragm into the liver, where there existed another abscess of a like size and character. Round about this abscess, and within the space of an inch from it, were several spheroidal masses, each about the size of a very small cherry, of a yellowish colour, and not unlike the caseous lumps in the lung. In the pleura of the under surface of the lung, in contact with the soft diffluent lymph, I observed, and recorded with illustrations in my work-book, the presence of cup-shaped depressions, bordered and lined with flattened nucleated epithelial cells. I did not at the time of examination understand the nature of these bodies, and was disposed to regard them as mere alveoli of mechanical production. The researches of Rechlinghausen, Ludwig, and Klein make it now probable that these bodies were temporary or permanent stomata. Besides these stomata communicating with lymphatic spaces, there were found other minute openings leading by tortuous channels into the pulmonary parenchyma. Nothing of importance was found in any of the other organs or tissues of the body.

CASE 10.—In May, 1878, a gentleman consulted me for severe pain in the left side, teasing cough, slight breathlessness on exertion, and recurring irregularity of heart. The patient was sixty-one years of age, spare, florid, dark-haired, light-eyed, and, although disposed to stoop a little, well preserved. He was regular in his habits, fairly moderate in the use of alcohol, active, and a considerable smoker. The family history was characterised by rheumatism, gout, heart disease, and asthma. In the past personal history of the patient the most notable events were indigestion, often recurring, rheumatism, some stray visitations of gout, and two or three attacks of pleurisy of short duration. The attack for which the patient consulted me was of a week's duration, and was ascribed by him to having got chilled whilst driving late in an open cab. The lower half of the left side was slightly contracted, and expanded imperfectly on inspiration; the tactile vocal fremitus was at most parts greatly diminished; there was complete dulness on percussion; grating friction and a superficial rustling crepitation obscured the normal breath sounds; the pitch of the vocal

resonances was lowered and curiously uneven. A few mucous rhonchi with sparse, coarse, moist crepitations were heard over the upper part of the same side. A few sibilant and sonorous rhonchi with large moist crepitations were heard throughout various parts of the right lung. The heart, drawn a little outwards, was weak and irregular; a systolic bruit was heard within both the mitral and the aortic areas. Nothing special was noted in the condition of the digestive, urinary, or nervous systems. Both hands, the knees, and certain parts of the spine exhibited osteo-arthritic changes. I had no opportunity of seeing this patient again until July, 1883, when, in conjunction with Mr. Gifford Ransford, I had charge of him until his sudden and unexpected death in March, 1884. In the early part of June, at Aix-les-Bains, the patient was seized with a sharp attack of pleurisy, and was placed under the care of Dr. Berthier. It is probable that the character of the thoracic signs led to a suspicion of fluid effusion, for I understood that an exploratory needle was used, and that no fluid was found. At the time of examination the patient complained of frequently recurring paroxysmal cough, ending in vomiting of muco-purulent, sometimes fetid, expectoration, of severe pain in the left side, of breathlessness on exertion, of night sweats, of slight fever, and of great prostration. The left side of the chest was irregularly contracted and flattened, and rose feebly on inspiration. Over the lower two-thirds there were diminished tactile vocal fremitus and complete dulness on percussion. The breath sounds generally were feeble, hollow, distant, and at most parts the vocal resonance was lowered in pitch and diminished in tone. At two places, one below the lower angle of the scapula, and the other about an inch external to it, the breath sounds were cavernous; the large moist râles had a metallic quality, and there was loud bronchophony. Throughout the upper two-thirds the percussion note was hyper-resonant; the respiratory murmur, of normal type, was loud, harsh, and accompanied by medium-sized moist crepitations; the vocal resonance was increased. Nothing abnormal was discovered in the right lung. The muco-purulent expectoration, of ordinary histological characters, contained areolæ of elastic tissue from the lung; but, although several times sought for, no tubercular bacilli were found. When the sputa were fetid micrococci were abundant. The heart, drawn upwards and outwards, was enlarged, weak, and irregular; at the place of impulse a loud systolic bruit was heard; and in the pulmonary area there existed another bruit, louder in pitch and fuller in tone. The temperature, falling in the morning, rose in the afternoon to 101°. There were slight chills and sweats. The digestive organs were much disordered; the tongue was loaded and the breath unpleasant. With anorexia and thirst, there was much flatulence; the bowels were irregular. The urine, at one time loaded with urates or depositing uric acid, was at other times limpid and slightly albuminous. Nothing worthy of notice was found in the condition of the nervous system. For months the patient steadily improved, and the condition of the left lung became quite passive. There were, it is true, occasional fits of paroxysmal coughing, some morning expectorations of the usual kind, and breathlessness or palpitation on exertion, but they did not materially interfere with the patient's comfort in life, and he did not himself give them any consideration. Curiously enough, however, as the condition of the lung and of the general health improved, the osteo-arthritic trouble returned, became slowly worse, attacked the neck, shoulders, back, hips, and hands, and was the cause of much suffering.

In February, 1884, the patient began to improve, and in the early part of March he had gained flesh and become in every way much better. But on the 10th of this month, being in his usual condition and exceptionally free from trouble, he suddenly began to cough up blood, and in a few minutes expired. The autopsy was made by Mr. John Morgan and Mr. Gifford Ransford. The whole left lung was united by layers of thick, dense, hard pleural lymph to the walls of the chest, and was removed with great difficulty. The lung was much diminished in size, dense and leathery to the touch, and invested by several layers of adventitious pleural membranes, varying in thickness and character at different parts. About the middle of the lung, where these membranes were thickest and most closely connected, they had, when cut, much of the aspect of a fibrous growth, and seen apart from their visceral connexions could have been easily mistaken for one. When laid fully open the lung appeared for the most part of a dark-red colour, and was found to be dense, hard, tough, and cut with difficulty. Fibrous bands passing from the pleura, and intersecting at various angles, traversed the middle portions of the lung, and compressed small bronchial tubes and bloodvessels. In the base of the upper lobe, and nearer the posterior than the anterior surface, there were two ragged irregular cavities. One, about the size of a walnut, contained curdy matter and blood; the other, rather smaller, was empty. Several bronchi in the neighbourhood contained clots of blood. The summit of the lung was encased in a thick capsule of laminated and indurated lymph; but the lung substance itself was substantially free from disease. Except at its anterior and inferior free margins, where there was much vascular emphysema, the immediate base of the lung although greatly congested and traversed by intersecting fibrous bands, was pervious to air, and free from any marked consolidation. The bronchial tubes were nowhere dilated. The right lung, beyond some pleural thickenings, exhibited no sign of disease. The bronchial glands were enlarged, but not caseous. The heart was enlarged, soft, dilated, and fatty. The mitral valve was rough, irregularly and finely nodulated, and incompetent. The aortic valves were atheromatous and incompetent; and the aortic lining was irregular, rough, and studded with patches and streaks of atheromatous deposits. In the sputum, many times examined during life, no tubercular bacilli could be found.

CASE 11.—In 1851 the patient, then a tall, stout, healthy bricklayer, forty-two years of age, with a good family history, fell from a scaffolding, and, having injured his right side, was admitted into the London Hospital, under the care of Mr. Luke. There it was found that he had fractured two of his right ribs and was severely bruised. After two months the patient was discharged from the hospital, and, although declaring himself well, had frequent cough, with blood-stained expectoration. In 1857 the patient came under my care for hæmoptysis. He was still stout and healthy-looking, and declared himself to be quite well, except for pain in the right side, a troublesome cough, and spitting of blood. A careful examination of the patient elicited no signs of disease, except in the right side of the thorax. There in the mammary and mid-axillary regions were slight dulness on percussion, increased tactile vocal fremitus, pleural grating, large moist crepitation, and moderately heightened vocal resonance. Coughing and deep inspiration produced sharp pain about the nipple. The pulse was 76, and the temperature 98·2°. In 1860 the patient again fell under my observation, and had altered much for the worse. He had become bald; his face, pasty and œdematous, wore an expression of suffering; his abdomen was loaded with fat; and he moved about with difficulty on account of shortness of breath. He still declared that there was nothing the matter with him but cough, profuse expectoration, pain in the right side, and dyspnœa on exertion. Inspection of the chest showed that the disease had considerably advanced since 1857. The right side of the thorax, between the clavicle and nipple, was retracted, and rose feebly on inspiration. The corresponding side of the neck was swollen, and the superficial veins, distended with blood, were not emptied during inspiration. In the retracted region there were found dulness on percussion, slightly diminished tactile vocal fremitus, pleural grating or creaking, bronchial breathing with coarse moist crepitation, and some increase of vocal resonance. These signs in more or less degree were found in the mid-axillary and scapular regions. In the summit of the lung the respiratory sounds were harsh and accompanied by crepitation; in the base no evidences of disease were found. The left lung appeared to be normal. The expectoration, which was abundant and gelatinous, or muco-purulent, consisted of a mucoid stroma having embedded in it leucocytes, blood-discs, granule cells, and epithelium. The heart was large, somewhat feeble, and beating at the junction of the cartilage of the fifth rib with the sternum. The pulse was 80; the temperature 98·8°. No notable signs of disease were found in any other part of the body. In 1866 the patient had lost flesh, strength, and colour, and his whole appearance suggested the existence of malignant disease. The face had a leaden tint; the features were full, and the under eyelids baggy with serum; the neck was swollen; the right arm was œdematous; and the right side of the thorax, greatly retracted, was covered by the ramifications of over-distended veins. The movements of inspiration were shallow, laboured, and frequent; the heart was seen beating to the right of the sternum, at its junction with the fourth rib; and periodical

paroxysms of cough, making the face livid and sometimes ending in vomiting, discharged quantities of muco-purulent phlegm. In this phlegm were found from time to time areolæ of elastic tissue from the pulmonary alveoli. Beyond some fine moist crepitations near the summit in front, nothing of moment was found in the left lung. Examination of the right lung yielded the results which follow. In the supra-clavicular region there were found hyper-resonant percussion note, increased tactile vocal fremitus, hollow bronchial breathing, prolonged expiration, crackling, clicking, and crepitating rhonchi and bronchophonic vocal resonance. In the infra-clavicular and mammary regions there were found great retraction of the thoracic walls, scarcely visible expansion on inspiration, diminished tactile vocal fremitus, blowing, and at some parts cavernous, breathing, clicking, crackling, and crepitating rhonchi and bronchophonic or pectoriloquous voice. In this region, also, the expiratory sounds were greatly prolonged, the rhonchi had a metallic quality, and pleural creaking or grating was sometimes audible. In the lung below these regions the respiratory sounds were jerking and harsh, the expiration was prolonged, and with both movements of breathing fine moist crepitations were heard. Percussion and the resonances were unaltered. The action of the heart, drawn, as already mentioned, to the right, was feeble and frequent. A low-pitched systolic murmur was heard at the base. The pulse, small and compressible, beat about 80 in the minute. No unsoundness was detected in the arteries. The extremities were cold, and the feet slightly œdematous. The tongue was loaded, appetite impaired, and thirst considerable. The liver was enlarged, and descended more than an inch below the free margins of the lower ribs. The bowels were irregular, and external hæmorrhoids sometimes distressed the patient. The urine was abundant and low in density. It contained about 5 per cent. of albumen, but deposited no casts. The skin was acting well, but there were neither night sweats nor chills. The evening temperature was 97·8°. About this time the patient was examined by most of my colleagues, and there was much discussion amongst us as to the nature of his malady; but the balance of opinion turned in favour of malignant disease. The patient remained for many months in the hospital. The physical signs of disease of the right lung continued after seven months substantially unchanged; but in all other ways, in appetite, flesh, strength, colour, and sense of well-being, the patient had become, to use his own phrase, "another man." Feeling thus much better, and anxious to get into some sort of work, he was, at his own request, discharged from the hospital. At the end of eighteen months the patient was found to be in extreme poverty, and becoming rapidly worse in health; and on October 1st he was re-admitted into the London Hospital. At this time the condition of the chest was much the same as when last examined; but in one or two places about the middle of the upper lobe of the left lung there were signs of fresh disease; slight circumscribed dulness, moist crepitations, jerking inspiration, increased resonances. The heart was still displaced to the right; there were systolic murmurs at the base; the pulse at the wrist was small, feeble, and under 80. The temperature was about midday 97·4°. It was, however, in his general condition that the patient had relapsed and become worse than at any previous time. With pallid and dusky hue of face, with greatly swollen neck, traversed by gorged and tortuous veins; with wasted body, and œdematous legs; with short and laboured breathing, interrupted almost to suffocation by paroxysms of cough; unable to move about without sweats and tremors—he looked the picture of suffering and weakness. The tongue was of a bluish hue, and thickly coated with a yellow fur; only fluid food could be taken; there was much flatulence; attacks of diarrhœa were frequent. The urine was of low density, moderately albuminous, and deposited granular and hyaline casts. The extremities were cold and blue. The skin acted freely and fell often into profuse sweatings. No notable sign of disease was discovered in the examination of the nervous system. Nothing done for the patient gave him relief. He became slowly weaker; and at length, after seventeen years' conflict with his malady, he succumbed. The thorax and abdomen alone were examined after death. The heart and great vessels lay beneath, and a little to the right of the sternum, corresponding to the third, fourth, and fifth intercostal spaces. The heart was large, soft, and loaded externally with fat; there was no demonstrable valvular imperfection; the lining membrane of the aorta and small portions of the pulmonary artery were atheromatous. The veins at the root of the neck were partially compressed by adhesions connecting the upper lobe of the right lung to the neighbouring parts. It was only by the free use of the knife that the right lung could be removed from the chest. Greatly diminished in size and irregular in form, surrounded by a tough fibrous capsule, at some parts over an inch and a half in thickness, and having disposed along its inner surface from the apex to near the base a flattened mass of lobulated yellow fat, the organ on superficial inspection looked more like a tumour than a lung. A longitudinal section having been made, it was seen that the fibrous capsule investing the lung consisted of several closely superimposed layers of different character and thickness; that, where uncut, the outer surface was rough, uneven, and obscurely warty; that from the inner layers fibrous bands of unequal breadth penetrated the lung, and passing along the inter-lobular septa, or accompanying the vessels, or surrounding the smaller bronchi intersected in various directions, produced an areola of varying size and form; and that chiefly at the intersections, but also occasionally elsewhere, the fibrous bands exhibited small, hard, tough, nodular swellings. Corresponding to the place where the ribs had been fractured, the adventitious pleural membranes were infiltrated with flakes and particles of calcareous matter. The upper two-thirds of the lung were intensely congested and riddled with small, ragged, irregularly-shaped cavities. Here and there were small consolidations due to the presence in the alveoli of an amorpho-granular obscurely fibroid matter. The pulmonary arteries, and at some parts the pulmonary veins, were thickened. Once in a lobular branch of the artery a nodule was seen almost entirely obliterating the lumen of the vessel, and growing from its inner wall. Almost everywhere the adventitia was thickened, not apparently by cell proliferation, but by a nearly homogeneous infiltration. In several instances in which small branches of the pulmonary artery were apparently much compressed or thickened, the alveolar territory to which it was distributed was in a condition either of fatty usure or of atrophic emphysema. This relation between the state of the vessel and the state of the lung was so frequent that one was disposed to regard it as causal. Some of the larger bronchial tubes in the upper part of the lung were dilated, whilst their walls had become thin and soft, but tough. At these parts the ciliated epithelium was replaced by a subspheroidal one, the cartilages were wasted and inelastic, and the muscles had apparently undergone fibroid degeneration. Here and there an early division of the intralobular bronchi was found almost obliterated, and the alveoli connected therewith were collapsed. Immediately beneath the pleura throughout the whole extent of its diseased portions the lung exhibited uninterrupted lines or patches of pneumonic consolidation. In the worst part the consolidation was of the croupous sort; but at several points where the consolidation was larger, and in immediate relations with lymphatic spaces or vessels, it was caseous. At some parts in the midst of the fibroid induration the alveolar walls were greatly altered in structure, and the alveoli contained a matter composed of free nuclei, leucocytes, epitheliod cells, and pigment globules. The alteration of the alveolar walls was considerable. They were thickened; the epithelium lining them was subspheroidal, and arranged sometimes in a single and sometimes in a double or even triple layer. Some of the alveolar capillaries were obliterated; others were dilated, almost saccular; all of them appeared to be thickened. The intervascular spaces, much larger than in health, had a fibrillated appearance, and were crowded with oval nuclei irregularly disposed. Once or twice an alveolar wall was seen to be nodulated; and both in structure and arrangement the nodule resembled a minute fragment of a nucleated fibroma. The lower third of the lung was intensely congested, and yielded on pressure an abundant frothy blood-stained muco-purulent matter. On its surface, and particularly at its free margins, the lung was emphysematous; but emphysematous patches were found also about the centre of the lung, close to, and sometimes in the midst of the fibroid induration. The left lung, of large size and a greenish-red colour, was connected by loose adhesions to the costal pleura. The whole lung was greatly congested, and yielded on pressure an abundant frothy sanguinolent serum. In the middle of the upper lobe there was a group of bodies which, in their naked-eye characters, could not be distinguished from what are called veritable

tubercles or grey granulations. About the size of a hemp-seep, spheroidal, and projecting above the level of the cut surface of the lung, they were greyish, semi-transparent, dense, hard, tough, and free from every trace of caseous change. Each body, composed for the most part of fibro-corpuscular elements, interspersed with epithelial-like cells and short nucleated fusiform fibres, might have been regarded, according to the subjective attitude of the observer, either as a mere fibrous knot or as a true tubercle. The irregular layers of new membrane constituting the capsule of the lung were of two kinds, but not alternately arranged. The one kind was hard, close, and similar to a lamellar fibroma; the other resembled a loose areolar tissue in the trabeculæ of which were branched connective-tissue corpuscles, and in the meshes thereof decaying leucocytes and epithelial-like cells. The bronchial glands were enlarged and loaded with pigment, but not caseous. The juice, in addition to the normal lymph corpuscles, contained in enormous numbers spheroidal multi-nucleated cells in a state of active endogenous proliferation. The liver and spleen were enlarged and congested. The capsules of both organs were greatly but irregularly thickened. In the former, cirrhotic changes were beginning. Both kidney were enlarged and much congested. Their capsules were opaque, thickened, and adherent. The capsular surface of each kidney was obscurely granular and mottled; but there was little wasting of the cortical substance. In many of the arteries, however, there was thickening of their outer and inner coats. I have in this case described some of the pathological changes found after death at greater length than the scope of these lectures will fairly warrant; but I excuse myself on the ground that they affect questions of fundamental importance, and that having followed the case throughout its whole course, I may venture, with less hesitation than will be necessary in the other cases, to deal with the conclusions which the study of the case seems to justify one in drawing from it.

CASE 12.—I now proceed to relate briefly the history of a case which in the group of advanced and complex cases represents that section of it composed of patients who have continued to live. This case is the last which I have chosen for the illustration of my subject, and at the close of the lecture it will be submitted to your own examination. The patient is unmarried and a potman, but, as is alleged, of temperate habits. The father died some years ago of consumption; the mother with a brother and sister are in good health. The patient himself never had any illness until September, 1875. About that time he had a chill, from which he speedily recovered. On October 28th, whilst walking in the street, he became suddenly cold, giddy, faint, powerless, and fell to the ground. Consciousness was retained throughout. Carried home and put to bed, he was seized with a sharp cutting pain in the left side, shortness of breath, dry cough, and recurring chills. On the 29th the patient recovered power; but after this time losing ground in other ways, he was received into the London Hospital on November 2nd. Examined after admission, the following facts were recorded. The left side of the thorax moves on inspiration less freely than the right; over lower three-fourths the tactile vocal fremitus is increased; and in the same region there are dulness on percussion, large moist crepitations, bronchial breathing, increased vocal resonance, and scattered patches of grating pleural friction. Examination of the right lung yielded no evidence of disease therein. Heart's action weak and frequent; pulse 94, small and compressible. Temperature 101°; respiration 28. The tongue was furred and dry; the breath was fetid; there was complete anorexia; the bowels were confined, and the urine was scanty, high coloured, and loaded with purple lithates. The skin was dry and harsh and the face flushed; the eyes were bright and the pupils dilated. The patient complained of headache, general pains, a sharp stitch in the left side, dry cough, and malaise. A week after admission an effusion of serum had occurred in the left pleura; the heart was pushed to the right of the sternum; and the patient's breathing had become rapid. Within a month all signs of fluid in the left pleura had disappeared; the heart had returned to its normal position; and, but for an uneasy sensation throughout the lower part of the left side, the patient said that he would be well. The pulse, respiration, and temperature were almost natural. Round the base of the lung, however, there were loud grating pleural frictions, and deep inspiration or cough produced pain. When the patient was dismissed, some months afterwards, the pleural frictions were still present, but he expressed himself as in other respects well. During the following year the patient was readmitted into the hospital with dry pleurisy of the right side. He was in poor general health, looked pale and ill, suffered from gastro-hepatic catarrh, and had scanty high-coloured urine, slightly albuminous, and free from sugar, but loaded with purple urates. The heart occupied its natural place in the thorax, was free from signs of disease, and beat about 80 a minute. Throughout the mammary and axillary regions of the right side there were grating or rubbing pleural frictions and pain on inspiration or coughing. The respiratory murmur was feeble and interrupted, and the resonances were diminished; but in as far as it could be ascertained there were no pulmonary râles. The left side of the thorax moved less freely than the right, and it was irregularly flattened. There was dulness on percussion in the infra-clavicular, mammary, axillary, and mid-scapular regions; the tactile vocal fremitus was slightly diminished; the breathing throughout was feeble and hollow; coarse moist crepitations, accompanying both respiratory movements, were heard in several places; and the vocal resonance, varying at parts, was on the whole increased. An inch below the outer end of the clavicle there was a patch of dulness equal in size to a florin, where there were heard bronchial, almost tubular breathing, a few small moist râles of metallic quality and bronchophony. Here and there intermittently pleural creaking or grating was heard. Patient had a short hacking cough, a moderate amount of muco-purulent expectoration, and breathlessness on exertion. The sputum consisted of a mucoid stroma, having embedded in it leucocytes, young epithelium, pus globules, granule cells, and much amorpho-granular matter in little masses or streaks. No elastic areolæ were found. A systolic bruit was heard in the pulmonary area; the pulse was 84; the temperature was 99°. The patient remained in the hospital until June, 1877. During all those months he improved in general health. The condition of the left lung remained without material change until the time of his discharge. And although on the right side the pleural frictions were often absent for weeks, they always returned for longer or shorter periods, and appeared to be causally connected with changes slowly advancing in the middle and lower part of the lung. In these regions the intercostal spaces were deeply retracted; there was diminished movement on inspiration; dulness on percussion had become considerable; the respiratory murmurs feeble, hollow, distant, resembled those heard in moderate pleural effusion, and vocal resonance was muffled. There was no displacement of organs; and various alterations of the position of the patient produced no perceptible change in the outlines of the area of dulness. On readmission to the hospital in 1882, the patient was found to be much worse than when he left it in 1877. Pale, thin, weak, breathless, he complained of troublesome cough, with a good deal of muco-purulent expectoration, and of acid and flatulent disorders of digestion. Furthermore, he had a small strumous-looking abscess over the second lumbar vertebra, and chronic enlargement of both testicles, unconnected with any venereal affection. On examination of the chest it was seen to be retracted, chiefly on the right side. Its movements during inspiration were shallow, frequent, and irregular, and the intercostal spaces were everywhere deepened. Over the upper half of the left lung there were dulness on percussion, slightly increased tactile vocal fremitus, pleural creaking, moist metallic crepitations, bronchial breathing, and increased vocal resonance. An inch below the outer end of the clavicle, and over a space of the size and form of a florin, there were to be heard cavernous breathing, large moist râles, and loud bronchophony. In the supra-clavicular region the respiratory sounds were merely feeble and hollow. In the upper third of the right lung no evidences of disease were discovered. The lower two-thirds were retracted, and rose little on inspiration. There was complete dulness on percussion; the tactile vocal fremitus was much diminished; the respiratory murmur was feeble; no râles were heard; but there were distinct pleural rustlings, creaking, and friction; the vocal resonance was muffled and distant. The state of the digestive organs was unsatisfactory; the tongue was coated and the breath fetid; the tonsils were enlarged, and stuffed with cheesy lumps; acidity, flatulence, and sensations of burning accompanied the digestive processes; the liver, rather small, was pulled upwards by the contracted lung; the bowels were irregularly and inadequately relieved. The urine, turbid from a little mucus, had a density

of 1016, contained about one-twentieth of its bulk of albumen, and, according to West's process, yielded with an average daily discharge 2 per cent. of urea. The heart, occupying its normal position, was slightly enlarged; at its base, within the pulmonary and aortic areas, a systolic bruit was heard; the pulse was 84, of moderate volume and strength; the arteries were soft. The evening temperature stood at 98·4°, the morning at 97·2°. The skin was rather harsh, dry, and indisposed to sweating. Nothing of moment was discovered in the examination of the nervous system. The morning sputum, not exceeding two drachms of muco-purulent matter, contained elastic areolæ from the pulmonary alveoli. The areolæ had become so changed as to admit of being broken by proper manipulation. In the sputum of the drier cough of the afternoon and evening moulds or casts of the tonsillar crypts were occasionally present. They resembled, but with ordinary care could be easily distinguished from, the elastic areolæ of the pulmonary alveoli. On leaving the hospital in 1883 the patient had greatly improved in flesh, colour, and strength. The digestion had become good; albumen was found only occasionally in the urine, and the percentage of urea had risen. The condition of the lungs had also improved; it is true that the physical signs of structural disease remained practically unaltered; but cough and expectoration had ceased, breathlessness was less, and the patient declared that he had no discomforts in his chest. When, in February, 1884, he again came under my professional care, he had again fallen into deplorable health, and was in every way worse than he had been at any former time. Thin and pale, bent and breathless, showing an uncertain gait and œdematous legs, it seemed as if his malady had greatly advanced, and as if life must be drawing to an end. Nevertheless, a careful examination was sufficient to show that, although there were cough, expectoration, and breathlessness, there was no material change in the actual physical condition of the respiratory organs. The patient's relapse was plainly due to failure in other parts of the organism, brought about by bad hygienic management, and by recurring bronchial and gastric catarrhs. The tongue was thickly furred; there were little appetite and much thirst; acidity, flatulence, weight, and pain frequently distressed the patient; the bowels were irregularly and inadequately relieved, and the fæces were deficient in bile. The urine, having a daily discharge of over fifty ounces, was pale, turbid with mucus, acid, of a density of 1014, and contained, according to the old tests, about a tenth of its bulk of albumen. The signs of a cavity under the outer end of the left clavicle had become much less marked; and the sputum, carefully and repeatedly examined, contained no elastic areolæ from the lung and no tubercular bacilli. The heart's sounds were muffled, seemingly from the development since last examination of some alveolar emphysema; the pulse was 104, small and compressible; the extremities were bluish and cold. The thermometer recorded an evening temperature of 98°. Once more under hospital care the patient rapidly recovered, and when discharged in August, 1884, he expressed himself well. No signs of active disease were to be discovered in the lungs; the digestion was good; albumen had disappeared from the urine; flesh, strength, and colour had been recovered; and beyond breathlessness on slight exertion the patient felt nothing of which he could much complain. On the 13th of March of the present year I examined for the last time the subject of this case. As usual after leaving the hospital, he had failed in health and become pale, thin, weak, and nervous. He complained of morning retching, of an occasional choking sensation in his chest, relieved by the "breaking of phlegm, which he could never get up;" of a slight, dry, hacking cough; of breathlessness on much exertion; and on epigastric cramp when he is hurried. He said, however, that he would be well but for the morning retching, and being closely examined with respect to this, he would not allow that it could be in any way connected with his manner of life. The tongue was furred, the breath foul, and the appetite capricious. Various discomforts were felt in the course of digestion, particularly a churning and burning, relieved by vomiting. The bowels acted daily, there were no hæmorrhoids. The urine, turbid when voided, was acid, phosphatic, moderately albuminous, and deposited after standing a flocculent sediment, consisting of phosphates, epithelium, pus cells, and some mucus. The head of the epididymis of each testicle was enlarged, nodulated, and tender. The thorax was irregularly flattened, from before backwards and from above downwards. The left side was more rounded, larger, and more movable than the right. The left clavicle was higher, and less prominent than its fellow; the shoulders were depressed; the breathing was shallow, laboured, abdominal, and very frequent. During inspiration the supra-clavicular spaces retracted. There was no venous engorgement of the neck. In the upper part of left side, in front and in the greater part of right side, the intercostal spaces in breathing are moved in the same manner as the abdominal muscles. Over the upper fourth of the left lung there were found diminished expansion; dulness of tympanic tone on percussion; generally increased, but at some spots diminished, tactile vocal fremitus; hollow bronchial breathing; at some parts a just audible vesicular murmur; and almost everywhere loud bronchophony. There were no râles; but in the lower and outer part of this region a superficial rustling, rubbing, or creaking could be occasionally heard. Between the third and sixth ribs there were found slight dulness of tympanic type, moderate tactile vocal fremitus, broncho-vesicular breathing, distant inspiratory crepitations, and diminished voice resonance. At the lower border of the sixth rib the gastric percussion note was heard. Over the summit of the right lung there were found diminished expansion, tympanic dulness on percussion, increased tactile vocal fremitus, hollow breath sounds, increased voice resonance, and no râles. From the middle part of the lung to its base, especially in the axillary region, there were found decreasing expansion, diminished tactile vocal fremitus, feeble bronchial breath sounds, pleural rustling or creaking, and muffled voice resonance. No râles were heard anywhere throughout this lung. The area of superficial cardiac dulness was increased. The impulse of the heart could be seen in the fourth intercostal space, just below and about an inch outside the nipple. In the second intercostal space, within an inch of the sternum, the auricular contractions were visible.[3] The first sound was muffled and mumurish, the second loud and reduplicated. The pulse was 94, small and compressible; the evening temperature was 98°. Except at the extremities, which were cold and damp, the skin was thin, rough, and dry. No sign of disease was discovered in the examination of the nervous systems. I have brought the patient here to-day, and he may be seen in one of the rooms below.

The justice of introducing this case as one of primitive dry pleurisy may be, I confess, fairly questioned. Sprung from a phthisical father, and the subject of strumous tonsils and testicles, some might plausibly contend, with the fashion of the time in their favour, that the primitive disease was tubercular, that the dry pleurisies were only its secondary manifestations, and that, arrested by fibroid evolution, substitution,[4] or invasion, the case was one of ordinary tubercular phthisis, which, in the felicitous diction of Dr. Moxon, was "writ old." But, more than this, it might be contended that as some of the lymphatic vessels arising in the deeper parts of the lungs empty themselves into the subpleural lymphatic spaces, tubercular changes among the lymphatic rootlets too far from the surface to be discovered by physical signs would manifest the earlier of their secondary consequences in subpleural adenitis or plastic exudations. And, furthermore, it might be asserted that in the beginning of this case tubercles did exist in the lung beyond the reach of physical exploration; that they excited secondary structural changes in the adjacent tissues; and that those changes, through the medium of the lymphatics, begot the dry pleurisies herein alleged to be primitive. All this, it is true, may be justly said. But it is also true that there is much to be said on the opposite side, and more than it would be proper for me to say on this occasion. Nevertheless, in passing, I may be permitted to remark that phthisical predecessors do not necessarily beget more than pulmonary vulnerability; that analogical arguments are not conclusive evidence; that facts ascertained upon evidence ordinarily considered adequate are not to be rejected upon merely theoretical grounds; that radical departures from all the several characters which collectively constitute a given type of disease demand, even if conditional, either a conclusive proof of unity or a separate recognition of autonomy; that the true criterion of the nature of a case lies less in the pathological

[3] Perhaps these movements were really due to a retracted lung and a dilated pulmonary artery.

[4] Cruveilhier, Boudet, Blase, Brichteau, and perhaps Pollock and Moxon.

changes which it exhibits after death, than in the completed history of its origin, course, and issues during life; and that if the case just recorded were made one with every other form of pulmonary phthisis, through the causal agency of a bacillus, loyalty to knowledge and service to society would alike require some more rational explanation than has yet been given; why, within the limits of a unity, real or imagined, forms of disease widely differing in their symptoms, signs, course, complications, duration, and issues should be refused a distinctive, although still dependent recognition. I do not know whether through this refusal the loss to science or to society is the greater; but I am sure the loss to both is great, and I shall advert to it again.

Here I must bring to an end this narration of cases. Every one of them represents but inadequately the group to which it belongs, and from none of them can be obtained a connected, and, as far as our present knowledge extends, a complete view of the subject matter of our inquiry. But when all these cases are collated, compared, and otherwise critically considered, one case will be found to illustrate or explain another, the more complete will in some measure supplement the less complete, and in the pathological changes found in those cases in which autopsies were made, we may fairly form probable judgments of the pathological changes which would have been found in other cases in which autopsies were forbidden. In this way it may happen that we shall at length succeed in getting larger and better knowledge than we now possess of the origin, course, and issues of dry pleurisies. And although it must be that this knowledge shall prove in many ways defective, and in some even inaccurate, it will at least suffice to provoke inquiry, and to make plainer and easier the way for those who follow in the search for what remains to be corrected and discovered therein.

A Museum Lecture

ON THE

ANATOMY OF SPINA BIFIDA.

Delivered in the University of Cambridge,

BY PROFESSOR HUMPHRY.

GENTLEMEN,—Finding considerable difference of opinion among surgeons respecting the anatomy of spina bifida, and especially, at which I was surprised, respecting the usual relations of the spinal cord and the spinal nerves to the sac, I have recently examined the specimens of this affection in most of the pathological collections of London, as well as some recent specimens which have been kindly submitted to me by Dr. Goodhart and Mr. Stewart. The chief points are, however, sufficiently demonstrated in the specimens before you, most of which were dissected and placed in the museum of the University by myself a good many years ago.

The name "spina bifida" is derived from one, and that not the most important, feature of the affection—viz., the separation or divergence, and in some instances the dwarfing, of the vertebral arches. This is associated with, and probably caused by, the protrusion from the vertebral canal of a sac containing a thin colourless fluid situated in the middle line, and of variable size. The affection is most common in the sacral, or the lumbo-sacral, region. The sac is more or less covered by skin, rarely altogether, but commonly to some extent of its circumference; the middle part being usually covered, rather formed, by a thin, translucent, bluish-red, more or less vascular, membrane; though in some instances this middle part has the appearance of a cicatrix. The thin, translucent, or cicatricial middle part is continuous with the surrounding skin, the line of demarcation between the two being pretty clearly defined. The sac is commonly circular in outline, and its upper and lower borders afford some criterion of the extent in the spinal column to which the vertebral arches are deflected, and the vertebral canal is open. Still, the sac not unfrequently overlaps the unaffected arches above and below, and it usually overlies and extends beyond the everted arches at the sides. Dissection in most instances shows the spinal cord turning beneath the lowest entire vertebral arch—that is, the arch immediately above the spina bifida, and passing into some part of the wall of the sac. In some cases the cord runs free through the upper part of the sac to the middle of its wall, where it is composed of the thin membrane just mentioned. In other instances, immediately upon reaching the sac the cord is blended with the wall of the sac, and requires a little dissection for its demonstration. The nerves, traced from the sacral, or the lumbar, intervertebral foramina, do not form a cauda equina in the usual manner, but are directed transversely, or nearly so, towards the same membranous part of the sac as the spinal cord; and, like the spinal cord, they are, in some instances, seen in their course to this part, lying free in the sac, whereas in others they lie in their whole length in the wall of the sac. In a third set of cases they present intermediate conditions, being partially free in the sac and partially embedded in its wall; or they are more or less united together by membranous bands which may be regarded as derivatives from the inner layer of the wall of the sac; and it is probable that the compartments, and even the cysts, occasionally found in connexion with spina bifida sacs may be thus produced. Thus, both cord and nerves pass to the sac, being stretched or lengthened in proportion to the size of the sac; and they are more or less blended with the thin membranous hinder part of it. In this specimen—at the lumbar and upper sacral region—the cord is seen entering the sac, traversing the upper part of its wall, blended with the hinder thin part, and then reappearing at the lower part, where something of a cauda equina is formed by the junction of the nerves of the two sides with the cord, and the median filament extends onwards towards the coccyx. The cord therefore in this case may be traced, and the anterior spinal artery is visible upon its surface, along the whole of the interior of the back of the sac, and from the sac into the sacrum; and the several lumbar nerves, from the two sides, pass on the wall of the sac to the cord. There was hydrocephalus in this case; and the central spinal canal, which communicated above with the distended cerebral ventricles, is dilated down to the spina bifida.

The nerve-roots and their ganglia in cases of spina bifida are not infrequently situated within the vertebral canal; and in some of the specimens before you, two or three adjacent ganglia are seen to be approximated and even joined together, and contained in one sheath of dura mater. This approximation and fusion are probably a result of the traction exerted upon the nerves in their passage upon the wall of the sac.[1]

The cavity of the spina bifida, which, as we have seen, is in some cases traversed by nerves and partitioned by membranous septa, looks in many specimens as if it were continuous with the arachnoid sac, and as if it were lined by the arachnoid membrane. In some this is the case. It is so in the dorsi-lumbar specimen I have just shown you. The sac of the spina bifida is here formed by a dilatation of the anterior part of the spinal arachnoid cavity, the posterior part of that cavity, the part behind the nerve roots, being obliterated, or not having been formed. But a careful and close examination shows, in some at least, perhaps in most of those in the sacral or sacro-lumbar region, that this is not the case. The parietal and visceral surfaces of the arachnoid in the spinal canal, near to the sac or at its orifice, may be seen to be adherent; or the epithelial lining is reflected from the one to the other, so that the arachnoid membrane is not traceable into the spina bifida, and the spinal arachnoid cavity is shut off from the cavity of the spina bifida. The sac of the spina bifida accordingly appears to be formed in the subarachnoid space, and the lining of the sac, as well as the coverings of the cord and of the nerves, and the more or less complete membranous septa, where these exist, must in that case be formed by the subarachnoid or pia mater tissue. It is not always easy to determine, even on dissection, whether the sac of the spina bifida is thus separate from the arachnoid cavity; but where it is so the fluid in the sac, and, in like manner, any fluid injected into the sac, will not readily pass into and along the arachnoid cavity of the spinal canal and the skull, though it may permeate the thin membrane which forms the wall of the sac, and so reach the arachnoid cavity or the loose subarachnoid tissue of the cord, and extend along the cord to the brain.

The specimen of lumbo-sacral spina bifida which I have

[1] This fusion of the ganglia was pointed out by Dr. Fisher, Downing Professor of Medicine in this University (London and Ed. Phil. Mag., vol. x., 516, 1837).

here, entrusted to me by Dr. Goodhart, and which has been recently dissected by Dr. Anningson, shows well many points of the anatomy of this malformation. The sac is of about the size of an orange, with the usual cicatricial tissue at the middle of its wall and with skin over the circumference. The skin and fat were easily removed near the spine, but are adherent to the subjacent layers of the sac near the middle, and ultimately blend with them in the cicatricial tissue. A tough structure, apparently the lateral halves of the interspinous ligament, cleft like the spinous processes, was found beneath the skin and fat on the sides of the sac. It was connected laterally with the recurved and shortened vertebral arches and spinous processes. The dura mater of the cord expands over the sac, forming a thick covering, pierced by the spinal nerves at the sides and blended with the other structures at the border of the cicatricial tissue. Beneath the dura mater is a double layer—visceral or spinal, and peripheral or subdural—of the posterior arachnoid (the arachnoid, that is, behind the nerve roots and the ligamentum denticulatum). These layers, though in close contact, were easily separated, the posterior arachnoid cavity being thus displayed. Like the other components of the sac, they are adherent and blended in the cicatricial tissue, and they are also closely adherent at the junction of the spina bifida with the spinal canal—at the level, that is, of the lowest complete vertebral arch; so that the posterior arachnoid cavity of the sac (in the wall of the sac) is quite shut off from the posterior arachnoid cavity of the rest of the spine. The visceral and peripheral surfaces of the anterior arachnoid (the arachnoid that is in front of the spinal nerves and the ligamentum denticulatum) were non-adherent; and the anterior arachnoid cavity was quite free along the whole length of the vertebral canal, including the spina bifida. The cavity of the sac is formed altogether in the anterior subarachnoid space, is entirely lined by subarachnoid or pia mater tissue, and is partially divided by imperfect septa of that tissue, projected into it by the spinal cord and nerves. A thick nerve-bundle, consisting of the spinal cord, with surrounding lumbar and upper sacral nerves, and forming, as it were, a retroverted cauda-equina, turns beneath the last vertebral arch, leaving the bodies of the vertebræ, the anterior dura mater, and the anterior arachnoid. Thus, invested with pia mater or subarachnoid tissue only, it runs for a short space free in the sac to the cicatricial tissue of the hinder wall of the sac; here the component cord and nerves, with their investing pia mater, are lost in the cicatricial tissue. The spinal nerves pass from the intervertebral foramina in regular order and pierce the dura mater separately all the way down from the head to the coccyx. The lower lumbar nerves having entered the dura mater, are, as we have seen, directed downwards, accompanying the cord to the back of the sac. The upper two sacral nerves, piercing the wall of the sac, take a more transverse course to the same point; and their ganglia, like those of the lumbar nerves, are outside the cavity of the arachnoid, and invested with sheaths of the dura mater. The nerve roots of the lower sacral nerves also pierce the dura mater, then run between the arachnoid layers in the wall of the sac—that is, in the posterior arachnoid cavity of the wall of the sac,—and so reach the cicatricial tissue; and the ganglia of their posterior roots lie in this posterior arachnoid cavity. Thus the wall of the sac is formed by the dura mater, the arachnoid, and the outer layers of the pia mater, together with the spinal cord and nerves; and the cavity of the sac is formed in the anterior subarachnoid tissue, and is lined, probably, by the endothelium of that tissue. Along the fore part of the vertebral canal the three coats, with the anterior arachnoid cavity, are undisturbed, and retain their normal relations with the bodies of the vertebræ, except that, as just said, the cavity is formed in the anterior subarachnoid or pia mater tissue, and a layer of that tissue is therefore expanded over the cavity; whereas at the hinder part of the vertebral canal, the three coats with the posterior arachnoid cavity, together with the nerves and the spinal cord, are stretched out to form the bulging wall of the sac, are more or less adherent to one another, and are all, as well as the cutaneous coverings, lost in the cicatricial tissue of the hindmost part of the sac. This specimen may be taken as illustrating the usual anatomy of a spina bifida, an accumulation of fluid in a cavity formed in the anterior subarachnoid or pia mater, with all the structures posterior to it—namely, subarachnoid tissue, spinal cord and nerves, posterior arachnoid membrane and cavity, dura mater, vertebral arches, subcutaneous and cutaneous tissues—stretched over it, and more or less imperfectly formed.

It is evident from the above anatomical considerations that the failure of development upon which spina bifida depends must occur at an early period of fœtal life, in most instances before the spinal cord has been segmented from the epiblastic, or epithelial, layer of the embryo from which it is developed. It accordingly remains adherent to that external epiblastic covering; the imperfectly developed tissues of the cord and of the nerves passing to it, together with this covering, form the membranous wall of the sac; and the various structures which should be produced between the cord and the epiblast are to a greater or less extent abortive. The failure may even take place, it is believed by some usually to do so, before the central spinal canal has been closed; or the recently closed canal may give way and be reopened by fluid accumulating in its interior; and in such case the median posterior exposed surface of the sac must correspond with the epiblastic tissue which should have formed the epithelial lining of the central canal.[2] This often cannot easily be determined, for the central canal becomes occluded where the cord joins the membranous wall of the sac, in the lower regions of the vertebral column at any rate; and its precise relations to the sac cannot therefore be made out. It was so in the specimen we have just seen, when there were hydrocephalus and dilatation of the central canal down to the spina bifida. The canal in this case could easily be traced down to the spina bifida, but no further; and it was impossible to say positively whether the structure which represented it was continued into the cord lining the sac of the spina bifida, or whether it was continued upon the external surface of the sac, though the appearances are in favour of the former supposition.

Associated with the failure of segmentation and development of the several structures between the cord and the epiblast is the accumulation of fluid, or dropsy, by the pressure of which the sac is formed, the vertebral arches are recurved or stunted, the nerves and the spinal cord are elongated, and the tumour is produced. It is possible that the dropsical condition, due perhaps to something of an inflammatory process, may be the prime agent, and that by its pressure it has prevented the segmentation of the tissues from the epiblast, as well as induced the other changes mentioned; or the dropsy may be due to a want of resistance consequent on the non-segmentation and arrested development of those tissues—that is to say, it may be cause or effect. The balance of opinion and of probability is perhaps in favour of the former view. Further, when several vertebræ above the sacrum are affected, the fore part of the spine, composed of the bodies of the vertebræ and the intervertebral substances, being unsupported by the vertebral arches and articulating processes, which are abortive or deflected, may bend backwards or forwards. In this specimen, in the loins, it is bent backwards; in this specimen, in the neck, it is bent forwards, so that the chin rests on the sternum; and in this third example, also in the neck, it is bent backwards, so that the occiput lies on the back. These several defects in the vertebral column, including the open state of the vertebral canal with the separation, eversion, or stunting of the vertebral arches, are all consequences of the arrested development and the imperfect segmentation and imperfect formation of the various structures in the median line, and of the dropsical accumulation associated with them. The greater frequency of this failure and of the presence of spina bifida in the lower—the sacral and lumbo-sacral—parts of the spine, is probably owing to the fact that the closing of the primitive furrow, which is a little dilated at this part, and other phenomena take place here rather later than in the upper regions; and they are therefore more likely to be interfered with or to be imperfect in this situation. A trace of this imperfection in the otherwise well-formed body is often to be seen in the smallness or incompleteness of the arch of the upper sacral vertebra, and also in the dimple in the skin over the coccyx.

I have thus described to you the anatomy of spina bifida, as it usually occurs in the sacral or the lumbo-sacral region; and you will have noted that the accumulation of fluid is usually in the subarachnoid space in front of the spinal cord, that the cord and the nerves are stretched backwards and outwards upon the sac, and are there confluent, together with the arachnoid, pia mater and dura mater, or their repre-

[2] See Contribution to the Study of Spina Bifida by Professor Cleland. Journal of Anatomy and Physiology, vol. xvii., p. 257.

sentatives, in the thin membrane which forms the hindmost part of the wall of the sac. Moreover, it is to be remarked that the cord, being unsegmented from this thin membrane and therefore fixed at this spot, and so fixed from a very early period of fœtal life, does not undergo that shifting in relation to the vertebral canal which ordinarily takes place during the later periods of fœtal life, and which is due to a greater proportionate growth of the vertebræ as compared with that of the cord. Hence the spinal cord, instead of terminating, as it does in the normal state, in the upper lumbar region, extends through the lumbar region into the wall of the sac, and may, in some instances, be traced beyond it to the lower part of the sacrum; and, as a sequence, the sacral and lumbar nerves pass transversely towards the cord in the sac, instead of ascending obliquely and forming a cauda equina; indeed, not unfrequently, as in a specimen I have shown you, the nerves traversing the spinal foramina just above the spina bifida take the reverse of their usual course and pass downwards, rather are dragged downwards, to the sac to join the cord. This, I say, is the usual disposition as demonstrated by much the larger number of specimens. In some cases, however, when the failure has occurred at a later period of fœtal life, the segmentation and the formative development of parts have taken place to a greater extent; and the skin, with its epithelium and the subcutaneous tissue, may have been formed in a natural manner all over the sac. This is the most frequent in the neck. In some, as in this lumbo-sacral specimen before shown you, the neural axis is more separated than in the other cases—that is to say, it is less completely fused with the wall of the sac, and forms a distinct cord or band attached along the whole of the inner surface of the hinder wall of the sac. It would seem, too, that in a few cases the segmentation and formation of the cord have been still more complete, so that it has become fully separated from the cutaneous and other tissues, and retains its normal place along the bodies of the vertebræ, and the dropsy, with the sac formed by it, is upon the hinder aspect of the cord. The cord then does not pass into the sac, at least does not pass along, and is not attached to, the hinder bulging wall of the sac. This would constitute a "hydro-meningocele" or "hydrorachis externa" posterior, in contradistinction to a "hydrorachis externa" anterior in which the cord and nerves enter the sac, and blend with its wall; and both these are to be distinguished from a "hydro-myelocele" or "hydrorachis interna," in which the fluid accumulates in the central spinal canal. It may be that this is so in a specimen in the museum of St. Bartholomew's Hospital. The specimen is a small spina bifida at the lower part of the sacrum, and the median filament of the cord and the nerves seem to be at the fore part of the sac; but further dissection is necessary to make the anatomy clear. In the College of Surgeons museum is a specimen from an infant who died three days after the application of a ligature to a cervical spina bifida. The narrow peduncle of the sac passes through between the sixth and seventh cervical spinous processes, which are almost fully developed, and nearly meet in the middle line. The cavity of the sac appears, from the direction of a bristle placed in it, to communicate with the hinder part of the arachnoid cavity, and the cord possibly is not in the least degree implicated, and passes free along the hinder surface of the bodies of the vertebræ. But further dissection is required to make sure of this. It may be, as in an apparently similar case represented in Förster's Misbildungen, that the affection consists in a dilatation of the central spinal canal, and that a thin dilated sheet of the hinder part of the cord is prolonged into the wall of the sac—that is to say, it may be an example of "hydrorachis interna." This can only be determined, if in such a specimen it can be determined at all, by removing the dura mater, and making a careful examination of the specimen. Whether the sac in this case was covered by skin or not cannot be seen. In cases of cervical spina bifida, occasionally met with, in which the sac has a narrow neck, and is covered by skin, the disposition is probably similar to that in the specimen just referred to. Like it, such cases furnish examples of the slightest degree of the malformation; and the examination of a larger number of specimens of the kind may enable us to judge what inference, as to the disposition of the cord and its relations to the sac, may be drawn from the presence of a covering of skin over the sac—whether, that is to say, the segmentation and development which have produced skin over the surface are associated with a corresponding segmentation and development of the cord sufficient to set it, with its pia mater and arachnoid, free from the sac, or so far free as to allow it to maintain its proper place in contact with the bodies of the vertebræ.

The fluid, as I have already said, appears commonly to be in the subarachnoid space in front of the cord; and the sac must in such cases, I conclude, be lined by an endothelium developed from that of the subarachnoid lymph spaces. In some instances the fluid is in the arachnoid cavity in front of the cord, and then the sac is lined by the endothelium of the arachnoid. The fluid may be, though this rarely is so, in the subarachnoid space, or in the arachnoid cavity *behind* the cord. In these last cases the cord would occupy its normal position upon the bodies of the vertebræ, and the nerves would also have their normal position; whereas in the cases in which the fluid, whether arachnoidal or subarachnoidal, is in *front*, the cord and nerves are separated from the bodies of the vertebræ, and are applied upon and coherent to, or blended with, the wall of the sac. The dura mater is in all instances expanded upon the sac, and traceable to the same extent as the skin, becoming like it, and at about the same place, lost in the homogeneous membrane of the hinder part of the sac. Though I admit that the fluid may be behind the cord, the cord retaining its normal position, I must say that I have not been able to satisfy myself that this was the condition in any one of the many specimens I have examined. In every one, unless the one presently to be mentioned be an exception, in which the anatomy was clear, the cord, or some part of it, and usually the nerves, passed into the sac, and was united with the wall of the sac.

In those cases where the vertebral arches are more extensively deficient, and which are often associated with deficiency of the vault of the skull and with more or less deficiency of the brain, the vertebral canal is usually covered only by a thin membrane, and the spinal cord, with the several superadjacent tissues, is absent or represented by that membrane into which the spinal nerves pass and are lost. In the specimen, however, which I now show you this is not the case. The fœtus is acranial and with spina bifida along the whole spine; the neck is bent sharply forward so that the back of the head is in contact with the dorsal part of the spine. The cerebral mass is quite rudimentary; and the axial cord, of considerable thickness, passes directly backwards from the floor of the skull, bridging over the concavity of the neck, upon the dorsal vertebræ, and is continued upon the bodies of the vertebræ along the whole length of the lower dorsal, the lumbar, and the sacral portions of the spine. The nerves join it in regular sequence; but in the neck they are crowded together, and the lower cervical ganglia on each side are blended into one mass invested by a common capsule of dura mater. In the upper part of the cord the central spinal canal is wide and open, forming a continuation of the fourth ventricle. It gradually diminishes to the lower dorsal region, where it is closed in as usual; and below this the cord tapers into the median filament which is continued to the coccyx. The specimen when it came into my hands, many years ago, was in its present condition; and to what extent the spinal central canal was dilated in the upper part, how it was covered in, what kind of covering existed over the spina bifida, and what was the cause of the eversion of the vertebral arches could not be ascertained. All that we can see is that the vertebral arches, without evident diminution of size, are thrown outwards and forwards, the vertebral canal is wide open in its whole length, and the spinal column is bent sharply forwards in the cervical region, and backwards in the dorsal region. The cord and the nerves lie on the bodies of the vertebræ in the sacral, lumbar, and dorsal regions, and pass, straight over the concavity of the cervical curve, from the dorsal region to the skull; and in this part where it bridges over the curve the central spinal canal is dilated. It is a remarkable case, and it appears to constitute an exception to the rule of the cord being closely connected with the hinder wall of a spina bifida, and to the ordinary manner of formation of spina bifida.

I say nothing about other exceptional varieties of spina bifida, such, for instance, as where there is cleavage of the bodies of the vertebræ, bony growths from them into the vertebral canal and other malformations. I have directed your attention chiefly to the more ordinary forms of spina bifida, the anatomy of which has acquired increased importance from the reintroduction of the treatment of the abnormality by injection. With reference to this treatment, you

will understand that it is better to introduce the needle, not in the mesial line, especially in the upper part, where the cord is almost certain to be connected with the wall of the sac, but on one side. Further, you will perceive that the separateness of the cavity of the sac from the cavity of the spinal arachnoid, in most instances, is some security against the direct passage of the injected fluid into the latter cavity, and that the advantage of Morton's fluid, as an injection, probably depends upon the addition of glycerine to the iodine and iodide of potassium, lessening the liability to the diffusion of those irritating substances through the delicate lining of the sac into the surrounding subarachnoid tissue.

ON THE

AFFINITY OF SIMPLE AND MALIGNANT JAUNDICE.

By J. WICKHAM LEGG, F.R.C.P.L.,
ASSISTANT-PHYSICIAN TO, AND LECTURER ON PATHOLOGICAL ANATOMY AT, ST. BARTHOLOMEW'S HOSPITAL.

In the January number of the *Revue de Médecine* there appeared an article by M. Chauffard on catarrhal jaundice, which was considered of sufficient importance to be noticed at length in the columns of THE LANCET. For my own part, I may say that I have read the paper with much interest and satisfaction, especially as M. Chauffard and myself had come to much the same views independently of one another. The two main opinions which the French observer sets forth are these: that catarrhal jaundice (a better name seems to be simple jaundice, because no theory of its cause is then assumed) is more of a general disease than is usually thought; and, further, that it is only one of a series of diseases, of which the lowest is the simple jaundice and the highest the malignant jaundice, the icterus gravis, or acute yellow atrophy of the liver. Though I have not followed exactly the same path, yet in one particular, at all events, as to the connexion between simple and malignant jaundice, I have arrived at the same point. So long ago as 1878, when writing in the St. Bartholomew's Hospital Reports,[1] I spoke of the affinity between simple and malignant jaundice. Pointing out that jaundice sometimes appears amongst kinsfolk or those living in the same house, it was said that in some of these patients the jaundice ran a harmless and uncomplicated course, while in others the jaundice first appeared to be as free from danger as in the rest, but later grave nervous symptoms came on, and the patients died. I added: "I am inclined to attribute the origin of the two to one cause—a poison introduced into the body in a greater or smaller amount; for we find that the epidemic jaundice appears in neighbourhoods where military ditches have been drained, or large diggings undertaken, or in the bad hygienic states which follow war or famine. Thus, if but a small dose of the poison be introduced into the body, only vomiting or diarrhœa may follow—a gastro-intestinal catarrh, followed by jaundice; or if the dose be greater or the patient predisposed, a malignant jaundice from parenchymatous changes in all the muscles and glands may prove fatal. The effect of a predisposition is well shown in the relation of the epidemics to pregnant women, nearly all of whom perish in an epidemic of jaundice, the state of their tissues predisposing them to the disease"—i.e., to the grave malignant jaundice. Much the same position was taken in a work on the "Bile, Jaundice, and Bilious Diseases" which I brought out in 1830. At p. 402, speaking of the difficulty of making a diagnosis between simple and malignant jaundice, it is said, "The line which separates these two must be very narrow ..... It seems to be a question of degree, not of kind." So far M. Chauffard and myself are in accord; we agree that the cause of the two diseases is a poison common to both; he thinks that in all likelihood the poison will be the septic alkaloids—ptomaines, as they are now called. This was an idea expressed by Gerhardt some few years ago, who thought that the acute yellow atrophy of pregnant women might be caused by the putrefaction of the dead fœtus.[2] But while of course acknowledging that the septic alkaloids may be the cause of simple and malignant jaundice in many cases, it would be a misfortune if they were to be looked upon as the only possible cause. It would be better to own that the causes are multiple. There are many poisons, organic and inorganic, which in small doses cause only a simple jaundice, in larger malignant jaundice. Amongst these alcohol stands pre-eminent for the frequency with which it causes attacks of simple jaundice, while on the other hand it does not seem to cause malignant jaundice so often as the other poisons akin to it in physiological action. It is well known that a debauch in wine will be often followed by a simple jaundice. On this point my experience is quite in accord with that of M. Chauffard. He found that an excess on what is now the national fête day, July 14th, was followed by a simple jaundice, while I have long been in the habit of pointing out at St. Bartholomew's that the festivals instituted by Sir John Lubbock are often followed by a small epidemic of jaundice amongst the out-patients. That alcohol will cause a malignant jaundice is shown by the classical case of Leudet. A man took by mistake a quantity of pure spirit, which act was followed by a three days' drunkenness; on recovery from this state he showed all the phenomena of malignant jaundice, both before and after death.[3] There are also other cases on record, though alcohol seems not nearly so prone to cause malignant jaundice as phosphorus or arsenic. In the chronic poisoning by alcohol, cirrhosis, its part seems to be to cause a general disease, of which the brunt falls upon the liver, which therefore draws to itself most attention, just as malignant jaundice used to be called acute yellow atrophy of the liver, and was considered a disease of the liver, though it is now by nearly all owned to be a general disease. Some years ago, in 1877, when speaking of a case of febrile cirrhosis in the St. Bartholomew's Hospital Reports, I stated some facts which seemed to me to point to the idea that cirrhosis of the liver was only a local expression of a general disorder, the outcome of a long-continued physiological action of certain poisons, which, when they act acutely and rapidly, cause malignant jaundice from parenchymatous degeneration; so that cirrhosis may really be looked upon as a chronic form of acute yellow atrophy of the liver.

A CASE OF EXCISION OF THE RECTUM FOR CANCER.

WITH REMARKS ON THE PREVENTIBILITY OF SUBSEQUENT CICATRICIAL CONTRACTION.

By HERBERT L. SNOW, M.D. LOND.,
SURGEON TO THE CANCER HOSPITAL.

SARAH W——, married, no children, aged forty-six, was admitted into the Cancer Hospital on Jan. 29th, 1884. There was no family history of cancer, but she was suffering from the effects of much mental trouble and hard work as cook in a hotel, lifting heavy weights, &c. Her husband failed in business four years previously. These facts are given as pointing to the frequent initiation of cancer by depressing emotion and debilitating nervous influences. The symptoms had been noticed for a year. On examination the rectal wall was found thickened and infiltrated as far up as the finger could reach; the mass was freely movable; beyond it the tissues appeared healthy. Much contraction existed towards the anus; there were great pain and difficulty in defecation. On Feb. 5th the diseased part was excised by the method recommended by Mr. Harrison Cripps, in his valuable Jacksonian essay. There was free hæmorrhage, checked without difficulty. The recto-vaginal septum was much infiltrated, and the dissection left this very thin. Subsequently iodoform was applied, and the patient placed in bed with the trunk elevated. The catheter was ordered to be used three times in the twenty-four hours; the wound to be syringed three times a day, and also after every evacuation, with a 5 per cent. boroglyceride solution; and a circular water-cushion, with marine lint filling the central aperture, to be kept under the pelvis. Four inches of the whole circumference of the intestine had been removed. The temperature records on the mornings of the next few days were as follows:—Feb. 6th, 101·4° F.; 7th, 100°;

8th, 100°; 9th, 99·6°; 10th, 98·6°. On February 11th two copious evacuations took place without medicine. The temperature subsequently did not rise above 99°; the bowels acted as a rule without aperient, and the patient rapidly regained health. She was not allowed to leave her bed till April 25th, and after two days was again sent back to it. On May 13th the rectal wound had entirely healed, but at the anal orifice there was a slight superficial excoriation. There was complete control of the evacuations, except when diarrhœa existed, and no difficulty whatever in defecation. The anal opening barely admitted the tip of the forefinger, a plug of intestinal mucous membrane filled it, and was visible externally. A small part of the recto-vaginal septum had sloughed away, leaving an opening into the vagina anterior to the new anal opening. The general health was good, and the patient was allowed to get up. On June 3rd it was found necessary to excise a recurrent ulcer of about the size of a threepenny-piece at the margin of the anal opening, and a smaller one on the fringe of mucous membrane at the edge of the vaginal perforation. Potassa fusa was subsequently applied rather freely. On July 8th the wounds had healed. There was necessarily much more rigidity at the anal orifice than before the second operation, and the patient could not retain her evacuations so well. On the 29th the note was: "No aperient has been taken for a week. The patient is very comfortable, with evacuations two or three times a day, the anal aperture becoming much more dilatable (now of the diameter of a shilling), closed by valvular folds of mucous membrane. The recto-vaginal septum is almost entirely obliterated in front of the new anus." On the 31st the patient was discharged well, and, to the best of my knowledge, there has been no further recurrence. In a short time she was able to resume her situation as cook, to hold her evacuations perfectly, except when liquid, and go about without wearing even a diaper. No bougie had ever been passed or required.

Remarks.—A grave stigma rests on the operation for excision of the rectum; while greatly prolonging, and often saving, the patient's life, it yet frequently leaves him with a permanent and very painful burden, owing to the cicatricial contraction which is only too apt to ensue. The above case, in which several inches of the whole circumference of the bowel were removed, was surely just such a one in which this disability might have been expected almost as a matter of course. The patient's immunity from it I am disposed to attribute simply to her having been kept rigidly in bed from beginning to end of her necessarily tedious convalescence. At the outset of this case it appeared to me that in the filling up of a large chasm with new fibrous tissue, and in the adaptation of this to peculiar functions, perfect rest must be a most essential element of the process; that, on the other hand, movement and pressure must necessarily irritate the organising tissue cells, and so probably originate the painful after-condition of which we often read. It is, of course, impossible to decide from this single case whether the above supposition is correct; but the rarity with which rectal cancer comes before the surgeon in a sufficiently early stage for excision must be my apology for publishing it. For if we can obviate the painful results of cicatricial contraction by the simple plan of keeping the patient in bed throughout the tedious convalescence, a great point will have been gained in perfecting the operation in question.

Norfolk-terrace, W.

TWO CASES OF POISONING BY CARBONIC OXIDE; RECOVERY.

BY JAMES MILLAR, M.D., C.M.

EARLY one morning in December last I was hastily summoned to attend two young men several miles in the country, who had been poisoned by coal gas. I could scarcely believe the messenger, but he insisted that such was the case. On my arrival I found two young men lying on the floor, rolled in blankets and packed with hot bottles. A. was of dark complexion, twenty-one years of age; and B. of fair complexion, nineteen years of age. On the previous night a fire composed of coal and coke had been kindled in their bedroom, and they were told not to close the door when they went to bed, because the room would be filled with smoke if they did so. A. went to bed, leaving the door of the room open; but B., having fallen asleep by the fire, rose in a sleepy state and closed the door. Both had been in bed for a considerable time, when the occupants of the next room were awakened by their stertorous breathing. They were unconscious, and had vomited freely during the night. The other inmates of the house had applied friction to the surface of the body, mustard to the legs, and hot bottles all round the body. When considerably shaken B. could speak, but immediately relapsed after giving an answer to a question. A. had never spoken, and could not be roused, and when I arrived all hope of his recovery had been given up. Both were cold and clammy, the surface of the body pale, and the conjunctivæ and mucous membrane of the mouth, &c., bright red. Both lay with their legs crossed and rigid. A. had his right arm so firmly flexed on his chest that it was almost impossible to unbend it; he was breathing stertorously. The conjunctivæ were insensitive to light and the pupils dilated. Pulse 40 per minute, sluggish, and easily compressible; respiration slow and laboured, and he could not be roused. B. had a small quick pulse, no stertorous breathing, pupils contracted. He could be roused for half a minute at a time, but not longer. He then complained of pain in the back and head, and relapsed into his former state.

At first I thought the poisoning must be due to something else, but from minute and careful inquiry, and the appearance of the patients, I was perfectly satisfied as to the cause. What to do had to be decided on at once. Friction and warmth to the surface of the body had been already tried, and were again had recourse to, but without any benefit. Artificial respiration was tried for some time, but had no good effect. A small quantity of brandy was poured into B.'s mouth, which he swallowed. The muscles of the lower jaw of A. were in a state of clonic spasm. His mouth was opened with difficulty and a little brandy poured in, which he also swallowed. The brandy caused vomiting in both cases, of which the patients were quite unconscious. The brandy was repeated. Ammonia, strong tea, and other stimulants had the same effect; they all caused vomiting and produced further depression. The doors and windows had been previously opened, so that there was plenty of fresh air. Venesection might have been done, as some recommend; but I have always failed to see that removing half the quantity of impure water from a vessel makes the remaining half purer. I believe venesection with transfusion would have been of service, but I was not prepared for that single-handed. Seeing carbonic oxide forms such a stable compound with the hæmoglobin of the blood, I thought a direct stimulus to the muscles of respiration might be of service, so with the end of a wet towel I commenced to flap the chest of B., when he soon began to cry out and sit up; this had a beneficial effect. After a further prolongation of the same process on A. there were a few deep inspirations, then he began to strike out in all directions, opened his eyes, sat up, and asked the cause of the disturbance. Both being now perfectly conscious, they were put to bed in another room, and after a few hours rest awoke with slight headache and feeling a little giddy. Next day they were perfectly well, with the exception of slight pain in the back and legs.

I am sorry my notes of two very interesting cases are so imperfect, but I had no time to take notes at the moment, and, having two patients to attend to at once, it was impossible. What I wish to draw attention to is the fact that stimulants made the cases worse, and, as latest authorities tell us, artificial respiration alone in such cases is useless. I believe what is wanted in such cases is a stimulus to the muscles of respiration, and the proceeding I have mentioned will be found to answer very well, where there is no time to procure assistance for the performance of such operations as venesection with transfusion, &c.

Arbroath, N.B.

HOSPITAL FOR EPILEPSY AND PARALYSIS.—At a meeting of the governors and supporters of this institution, which was held on the 25th inst., it was stated that there had been a marked increase in the number of in-patients during the year, the total having been 141, as compared with 78, 64, and 125 in the preceding three years, whilst the "attendances" of out-patients had been 7688, as compared with 7531 in 1883. The receipts from all sources during the year were £2439, out of which there remained a balance of £80, or the same as at the close of the preceding year.

MIDDLESEX HOSPITAL.

A VERY LARGE UTERINE FIBRO-MYOMA, TOGETHER WITH THE UTERUS, ITS APPENDAGES, AND BOTH OVARIES, SUCCESSFULLY REMOVED BY ABDOMINAL SECTION.

(Under the care of Mr. HENRY MORRIS.)

THIS case will be found interesting from several points of view, and illustrates well the modern advance of surgery in the direction of the removal of large uterine tumours by abdominal section, and is a good example of the mode of doing so, and of the after-treatment. It will be seen that the pedicle was secured by a clamp, and retained outside the abdomen, in contrast to the treatment of the pedicle in ovariotomy, which is secured by means of silk ligatures, and replaced in the abdominal cavity. Some prefer the use of a drainage-tube in addition to the extra-peritoneal treatment of the pedicle after removal of uterine tumours. The mortality after the removal of uterine fibro-myomata has been very high. Dr. Bigelow, in March, 1884, collected a list of 359 operations, the records of which had been published, with only 227 recoveries, there being a mortality of more than one in three. Should the cases which have been operated on during the last year be added to the list, the percentage of deaths will be found considerably reduced. Removal of the uterus and its appendages for fibro-myoma cannot be classed with those cases in which it is removed for cancer. In both the mortality is high, but when the former has been removed the patient need fear no recurrence, whilst in the latter recurrence usually takes place in a painful form within a few months, and the general opinion of the profession appears to be that the operation for cancer should be abandoned. For the report of the case we are indebted to Mr. W. Roger Williams, surgical registrar.

The patient, a moderately nourished, healthy looking, fair complexioned woman, aged forty-eight, was admitted with a large abdominal tumour. She complained of weakness and of a feeling of sinking at the pit of the stomach, and of pain in the left iliac region. On examination the whole abdomen was greatly distended, especially at its lower part. The greatest girth, a little below the umbilicus, measured forty inches. A large, smooth, elastic, but non-fluctuating mass could be felt, filling almost the whole of the abdomen; it was slightly movable. There was tenderness in the left iliac region. On percussion of the front of the abdomen, with the patient supine, dulness extended from the symphysis pubis to within two inches of the xiphoid, in the middle line. Laterally the dulness extended over a widening area from above downwards, until it included the whole of the front and lateral parts of the abdomen. Both loins were resonant. On vaginal examination the os uteri was very high up, almost out of reach of the fingers. There was no vaginal discharge. The patient says she first noticed a slight swelling at the lower part of the abdomen fifteen years ago, but it was not more on one side than the other; this has since slowly increased. It caused her no inconvenience, except from its weight and bulk, until a few months ago, when she became subject to occasional attacks of pain in the left iliac region. During the last month she has suffered much from this pain. The day before admission she fell and sustained a scalp wound, but thinks that the abdomen was not injured. Her previous health has been good; she can recollect no serious illness since childhood. She married at twenty-five, and had one miscarriage three years afterwards. She has never since been pregnant, though she has continued to live with her husband. The catamenia first appeared at the age of fourteen and a half, and continued regular until she was forty-six years; since then she has occasionally seen a little sanious discharge at irregular intervals. Of her parents she knows nothing. She is one of a family of four; a sister died of cancer of the uterus, aged forty-four; the others are dead, but she does not know the causes of death. She was born at Cripplegate, London. She had been for eight or nine years under the occasional observation and treatment of Mr. Morris, who was at length determined to the operation by the constant and often severe pain in the left iliac fossa which had of late been suffered. This pain was aggravated by the slightest movement, and was not completely relieved by absolute rest in bed. Nearly a month after admission, during the greater part of which time she had been kept in bed, the operation was performed. A longitudinal incision two inches long was made in the median line of the front of the abdomen, midway between the umbilicus and the pubes. On examination of the tumour through this wound it seemed to be free from adhesions in front. The incision was prolonged a little upwards and downwards. When proceeding in the latter direction care was taken to avoid injuring the bladder. This organ, however, never came in the way during the operation. The great omentum was now found to be adherent to the upper part of the tumour, and in it there was a cyst containing clear fluid. In raising the tumour out of the abdomen a small rent was made in its left side; immediately the blood gushed out in a torrent. It was arrested by pressure with the thumb. The external incision was further extended upwards; it was now six inches and a half long. The bowels were protected by flat sponges in the peritoneal cavity. The tumour was then turned out of the abdomen with the omentum still adherent. The latter was clamped and divided; its bloodvessels were very large; there were six or seven veins as large as the external jugular. The tumour was now held to the uterus (which was raised high out of the pelvis) by a pedicle about an inch and a half in diameter. This was clamped with Kœberlé's serre-nœud, and the mass was cut away. It weighed nineteen pounds. It was a solid tumour, for the most part smooth on the surface, but presenting at its lowest part several rounded nodulations. Here was the body of the uterus, greatly enlarged, with half a dozen fibroids in its walls, varying in size from a small walnut to a large orange. Portions of each Fallopian tube were also adherent to it; but the bulk of the tumour was due to a single enormous fibro-myoma, presenting the ordinary characters of that kind of growth. Both ovaries and the remains of the Fallopian tubes were next removed. The left ovary contained five small cysts. The left Fallopian tube was greatly distended, tortuous, and adherent to the left side of the pelvis, so that it could not be entirely removed. The right ovary was normal. The division of the pedicle had passed through the cervix uteri. On examination of the stump it was found to contain three small fibroids; these were enucleated. Lawson Tait's clamp was then applied to it close above the vagina, and the distal part was cut off. The abdominal wound was closed by superficial and deep sutures, and the pedicle was left projecting from its lower angle. The wound was dressed with boracic lint and iodoform wool, and over these the usual abdominal flannel binder. The operation lasted about an hour. Chloroform was commenced at 9.45 A.M.; the patient was comfortably in bed by 11.10 A.M. During the first week after the operation the temperature ranged at about 100° F.; it never went above this. During this period all urine had to be drawn off with the catheter. It was turbid, alkaline, and contained muco-pus. At first she complained of pain, thirst, and flatulence; and she was occasionally sick. Morphia suppositories and hypodermic injections were administered. On the third day a troublesome hacking cough set in, and on that day the dressing was first changed. Subsequently it was changed every day for a week, and then every other day. During the first three days after the operation she took only small quantities of ice and milk; on the fourth day some jelly beef-tea was added; on the sixth a slice of bread-and-butter, and subsequently other things. Purulent vaginal discharge was noticed on this day, so a plug of iodoform wool was introduced into the vagina and changed daily. During the second week the temperature ranged from 98° to 99° F., and subsequently it remained nearly normal. On the first day of this week eight of the deep sutures were removed, and two of the superficial ones. The bowels were first moved about the middle of this week after two enemata. Catheterism still required, though occasionally she micturated without it. On the eighteenth day after the operation the clamp was taken off and the distal fragment of the pedicle came away, and the last two of the deep sutures were removed. After this catheterism

was seldom necessary. In a week the wound was quite healed, with the exception of a few granulations at its lower part. She left the hospital convalescent five weeks later.

MANCHESTER ROYAL INFIRMARY.

CORXISTING RENAL AND BILIARY CALCULI, CHOLECYSTOTOMY; DEATH; NECROPSY; REMARKS.

(Under the care of Mr. G. A. WRIGHT.)

FOR the following notes we are indebted to Mr. V. Wigglesworth.

Thomas C——, aged forty-four, was admitted under Mr. Wright's care on Jan. 2nd, 1885. He had previously been an out-patient for some weeks. He had been a healthy, temperate man till two years ago, when he was seized with severe pain in the right groin. At this time his urine was muddy; but it is doubtful whether this was from the presence of blood or merely from lithates; however, the pain decreased when the urine was thick. This state of things went on for a year with intermissions. Seven months ago he entered the Leeds Infirmary, and was discharged after a fortnight, temporarily relieved. A month later the pain returned, and he therefore came to Manchester as an out-patient. The diagnosis was made of probable renal calculus. He improved for a time with lithia, but soon the pain and inability to do any work made something more radical necessary. Mr. Wright therefore took him in. On admission he was a rather thin, worn-looking man, whose main complaint was of a fixed pain about midway between the right kidney and the bladder in front; there was sometimes pain in the right loin. He was always able to pass urine easily and without pain; no gravel; he never had jaundice or any other liver trouble; bowels natural. He was quite unable to work. Urine strongly alkaline, with large phosphatic deposit; no albumen, blood, &c. There was tenderness on pressure over the painful spot, but no tumour could be felt. The right kidney region was distinctly more tender and resistant than the left, but no enlargement could be felt. After admission he was somewhat easier while lying in bed, but on getting up for an hour the pain was increased. Diagnosis as before: calculus probably in ureter. The urine (sp. gr. 1014) became acid on taking benzoate of ammonia, but no improvement resulted. On January 29th the right kidney was explored through a lumbar incision made first obliquely downwards from the costal margin, and subsequently enlarged by incisions along the last rib and crest of the ilium. On reaching the kidney it was not enlarged, but an abnormally hard spot was felt in the region of the pelvis. Next the fingers were passed downwards and forwards after making the lower incision towards the painful spot in the groin, and here a hard mass moving freely with respiration was felt. With some difficulty this was drawn up to the wound, and was at first thought to be a calculus in the ureter. The cyst wall covering it was incised and the calculus removed. It was then found to be a gall-stone lying in a large cavity with smooth walls—the gall-bladder. The edges of the opening in the bladder, which contained no fluid, were stitched to the skin, and as the stone corresponded almost exactly to the seat of pain the kidney was not further examined. The gall-stone was as large as a pigeon's egg. On the second day the patient developed evidence of acute peritonitis, and gradually sank, dying on February 3rd. The last dressing, on February 2nd, showed slight bilious discharge.

Necropsy.—Lungs: Both bases congested; some old adhesions. Abdomen: Recent acute peritonitis; lymph and pus most abundant in the right loin. Gall-bladder pulled down and adherent by its apex to the wound in the loin, to which it was united by sutures and recent adhesions; old adhesions, however, bound it down to the abdominal parietes nearly as low as the groin. The liver was drawn downwards and towards the right, and tilted, so that its upper surface looked almost directly forwards; it showed old marks of peri-hepatitis, but was otherwise healthy, though pale; it weighed fifty-six ounces. The gall-bladder was greatly enlarged and contained mucus, but no bile or gall-stones; the cystic duct was quite patent, and could have been obstructed only by the flexion resulting from the position of the liver and gall-bladder. Kidneys each weighed six ounces; the capsules were slightly adherent; cortex fairly normal; slight pyelitis in the left, more marked in the right. In the pelvis of the right kidney corresponding to the firm spot felt during the operation was a pyramidal calculus the size of a hazel nut, with its apex in the ureter; the stone was smooth, and apparently composed of uric acid. Bladder and ureter healthy.

Remarks by Mr. WRIGHT.—The case is remarkable from the unexpected coexistence of the two calculi, and we were led away from the correct opinion formed before the operation by finding the gall-stone, which apparently fully accounted for the pain, and which was practically his only symptom. I am not aware of a similar complication having occurred; though, as my friend and colleague, Dr. Steell, has pointed out to me, the coexistence of renal and biliary calculi is common, as recorded by Murchison and others. Probably in any case, with both kidneys damaged, a bad result would have followed; but the fact is worth bearing in mind. Mr. Whitehead and Mr. Southam helped me at the operation.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Discussion on Cholera.

AN ordinary meeting of this Society was held on Tuesday last, Dr. George Johnson, F.R.S., President, in the chair. The meeting might well be termed extraordinary, both in point of the number of individuals present and in the wealth of the display of specimens illustrating the bacteriology of cholera. Specimens were exhibited by Dr. Klein, Mr. Watson Cheyne, Dr. Warden, Dr. Heron, and Dr. Thin.

Dr. GEORGE JOHNSON read a paper on the Etiology, Pathology, and Treatment of Cholera. The object of the communication was to submit for discussion the main points relating to the etiology, pathology, and treatment of that disease. Cholera is believed to result from the action of a specific contagium or morbid infecting agency, which may enter the system either with the air through the lungs, or with food, water, or other liquids through the alimentary canal. Facts were mentioned which tend to prove that the contagium enters the circulation, where it probably undergoes increase at the expense of some blood constituents, which are then excreted through the mucous surface of the alimentary canal, and are ultimately expelled by vomiting and purging, and thus the patient recovers. In the more severe cases collapse occurs. That collapse is not the result of the liquid discharges from the system is shown by the notorious fact that in the most rapidly fatal cases there is rather an inverse than a direct ratio between the degree of collapse and the amount of the liquid discharges. A complete arrest of the discharges during collapse is a sign of fatal import; while, on the other hand, there is a continuance of the discharges in a greater or less degree during recovery from collapse. The effect of various and opposite modes of treatment is also inconsistent with the theory that the worst symptoms are the result of the liquid discharges. Those methods of treatment appear to have been most successful which have been least repressive in their tendency. The sudden onset and the rapid passing away of extreme collapse are inexplicable by copious exhausting discharges. That the main and essential cause of choleraic collapse is a greatly impeded circulation through the lungs is proved by the appearances found after death, and by the complete explanation thus afforded of the chief symptoms of collapse. When the chest is opened soon after death in collapse, the left cavities of the heart are found nearly empty, while the right cavities, the pulmonary artery, and the systemic veins are distended with blood. Extreme contraction of the pulmonary arterioles is the only probable explanation of this arrest of the circulation. The blood thickening is the consequence, and not the cause, of the impeded circulation. The small stream of blood through the lungs during collapse, with the resulting defective oxidation, explains the suppression of bile and urine, while in the case of nursing women the mammary secretion, which is not an oxidised product, continues. The marvellous temporary relief afforded by injecing a hot saline solution into the veins is due to the warmth of the liquid relaxing the arterial spasm, and thus allowing the blood to pass on; while the beneficial effect which has often resulted from venesection is explained by its lessening the distension of the right cavities of the heart, and so increasing their contractile power. Reference was made to

other causes of arrested pulmonary circulation—pulmonary embolism, exclusion of air, and the inhalation of nitrous oxide gas. The intestinal discharges are the means by which the disease is conveyed from the sick to the healthy. In this respect there is a close resemblance between cholera and enteric fever. With regard to prevention, it is believed that quarantine is as powerless to exclude cholera as to shut out typhoid fever. The true preventive means consist in the enforcement of cleanliness and the complete disinfection of the choleraic discharges. An indiscriminate opiate and repressive treatment in the diarrhœal stage is believed to increase the danger of collapse by preventing or retarding the escape of the morbid poison. An evacuant or cleansing method is consistent with the true theory of the disease, and has been amply justified by a large experience, more especially by such results as have been recorded by Drs. M'Cloy and Robertson in a paper published in the fiftieth volume of the Royal Medical and Chirurgical Transactions. The object and the results of a rational evacuant treatment are, not to increase the discharges from the blood into the alimentary canal, but to prevent the retention and to quicken and facilitate the expulsion of offensive morbid secretions from the stomach and intestines. That treatment of choleraic diarrhœa is the best which most speedily arrests the discharges without subsequent ill effects. On the other hand, the only safe use of opium is to allay irritation after the expulsion of noxious materials.

Dr. KLEIN said that there could be no doubt that epidemics of cholera were the result of importation from localities the seat of cholera. The point to be determined was, What was the infective agency? In some cases the linen and clothes were the means by which cholera was conveyed, and an epidemic investigated by Hirsch at Wildhausen in 1873 showed that importation had taken place from the United States; the clothes and linen came from the infected locality; these articles had not been worn by cholera patients. Again, persons not sick of cholera may convey the disease from one part to another, which proved that the infective agency was not necessarily associated with the cholera dejecta. The infective agency must be a living entity, because it is capable of undergoing self-multiplication, and nothing merely chemical possessed this power. The question had to be decided whether the infective agency was identical with the virus of cholera; whether cholera belonged to the class of true infectious diseases, like anthrax, tuberculosis, gonorrhœa, &c. Or whether the micro-organisms were the generators of the actual virus; whether the infective agency lived and multiplied outside the body, as was the case in septic poisoning, where bodies called ptomaines were the real virus. He believed that cholera belongs to the second class of infectious diseases. The incubation period of cholera may be half an hour to a few hours, and, if so, it was impossible to believe that in such a short space of time micro-organisms could accomplish the result. A chemical ferment formed outside the body, and when absorbed was the real poison at work in cholera. This chemical virus acted on the blood and nervous tissues, and gave rise to all the phenomena of cholera. From all his experience, he concluded that the bodies of patients suffering from cholera do not contain organisms which could be regarded as specific and pathogenic, and in this he was directly opposed to Koch. In all true infectious diseases the organisms were present in the morbid products in great numbers, but such was not the case with cholera. When it was remembered that linen not soiled can convey the infection, and that water which had come in direct contact with choleraic discharges did not produce the disease, he considered that his position was rendered still more secure. In ordinary non-epidemic times emanations from sporadic cholera gain access to the water in tanks, and this water is drunk by by those who dwell round the tanks, yet no epidemic appeared, as he could testify. Benares, which was a filthy town, was a site where sewage was discharged into the river, and where the natives, bathing in the Ganges close to the outlet of a sewer, and even drinking the water, yet remained free from any epidemic of cholera. These facts proved that the evacuations of cholera were harmless. In hospitals devoted to the treatment of cholera the attendants remain unaffected as a rule; but, as Pettenkofer pointed out, the hospital itself sometimes becomes a cholera locality, and then the residents in the hospital are as liable to cholera as other individuals. The virus of cholera is not present in or dependent on the dejecta of cholera, but its formation is dependent upon locality, as Pettenkofer has maintained. These views were in irreconcilable antagonism with contagionists such as Koch. In beginning his researches on cholera, Koch was struck by the peculiar shape of the comma bacillus, and it was the morphological peculiarity which first led him to say that the comma bacillus was specific; but since the same shaped bacillus had been found in other normal and abnormal conditions, Koch had altered his standpoint. The more typical, the more acute, the case of cholera, the more numerous were the comma bacilli, according to Koch. But he (Dr. Klein) had not confirmed the statements of Koch, for he had found that the bacilli were exceedingly scarce in some fatal cases of cholera. Koch had asserted that the bacilli were chiefly found in the lower part of the ileum, and that Peyer's glands were specially affected in this region, whilst the intensity of the disease diminished the further we went away from the lower part of the ileum. The appearance was not different at this part of the ileum, so far as he (Dr. Klein) had made out, for the whole small intestine was filled with clear watery fluid, in which mucous flakes floated, and there was no distinct difference between one part and another of the small intestine. Though he agreed that the comma bacilli specially affected the lower part of the ileum, the bacilli could not be specially connected with the disease, seeing that the whole of the intestine was equally affected, and yet the bacilli prevailed only at one part. Nor was it possible that the comma bacilli produced a chemical poison, for the quantity of the poison should be dependent on the number of bacilli; but in some fatal cases the comma bacilli were exceedingly scarce. With regard to the presence of the bacilli in the wall of the intestine, he denied the statement, and had found no other organism in the tissue of the intestine. This fact was also testified to by the French Commission, which had been able to verify the presence of the bacilli only in dead tissues. So that having regard to these points, and to the scarcity of the bacilli, he concluded that the bacilli can have nothing to do with the cause of cholera. Koch had affirmed that in the mode of their growth in cultivation media this comma bacillus was special and peculiar, and cultivation served to isolate it from other kinds of bacilli. Even here Dr. Klein was not disposed to agree with Dr. Koch that their growth was peculiar and specific, for he knew of other organisms found by Dr. Timothy Lewis in the salivary secretion which presented similar appearances, as the tubes shown by him at the meeting were held clearly to demonstrate. The comma bacillus, if it were a definite species, could not be shown to be pathogenic by its behaviour in solid nourishing material, though by the growth in solid media we could recognise with the unaided eye different varieties of comma and other bacilli. Referring to the water-tank incident in Calcutta, he said that there were 200 families living in huts around this tank, and on February 13th, 1884, Koch found comma bacilli in the water; but the epidemic had lasted more than a month, and the cholera dejecta were constantly thrown into the tank; so that he thought it logically absurd to conclude that the bacillus was the cause of the cholera. Now he (Dr. Klein) was present at the beginning of November, 1884, at the same tank, and not one case of cholera occurred in the dwellers around the tank, and yet the comma bacilli were present in the tank and the water was unquestionably drunk by the people. Coming next to the experiments on animals, he said that Koch had had nothing but negative results. Nicati and Rietsch had obtained some results; but was it cholera that they had induced in animals as the result of the injection of comma bacilli? Ligature of the bile-duct was practised by these observers, and it was suggested by Friedländer that this had been done because there was no bile in the intestines in cholera. He suggested that tying the ureter might just as well have been done on the plea that there is suppression of urine in cholera. In some of these experiments on animals positive results were obtained, and the symptoms resembled those met with in what the French term "choléra foudroyant." In these cases (dogs were used) the comma bacilli grew and multiplied in the small intestine, but he would have been surprised if such had not been the case. He questioned, however, whether the induced disease was cholera; might it not have been a form of septicæmia? In guinea-pigs, also without ligature of the bile-duct, positive results had been obtained, and at the post-mortem examination detached epithelium, mucous flakes, and hyperæmia of the mucous membrane were discovered; but such appearances were very commonly witnessed in septicæmia. Koch, working afresh on dogs

without ligaturing the bile-duct, had succeeded in causing certain symptoms followed by death in three days, and here the intestines were hyperæmic and the canal contained a watery fluid. But were the experiments performed antiseptically? In India he (Dr. Klein) had injected syringefuls of the comma bacilli into the jugular vein, the intestine, under the skin, and into the peritoneum of rodents, cats, dogs, and monkeys with purely negative results; he had also employed cultivated comma bacilli. Mr. Horsley and Mr. Dowdeswell had worked at the subject also, and with similar negative conclusions. But even allowing that the experiments on animals yielded sometimes genuine results, does it prove that the organisms are pathogenic as regards man? Rodents were liable to a form of septicæmia due to organisms which, however, were not pathogenic to man. He next referred to the existence of certain minute straight bacilli in connexion with lymph corpuscles and mucous corpuscles. He had detected these organisms only in cases in which the autopsy was made within two hours after death, and they were the only organisms discovered which had any relation with actual living tissues. He ventured to think that if Koch had detected these minute straight bacilli, he would have regarded them as pathognomonic of cholera. These bacilli were detected by the ordinary methods of staining. He suggested that Koch had missed them because his autopsies had not been made as early as they might have been done. These bacilli grew chiefly on the surface of the solid media, They did not liquefy the gelatine like putrefactive bacteria In conclusion, he summed up his views by asserting that the infective agency of cholera was extraneous to the body, that it had its breeding-ground in a suitable soil, and that it produced a chemical virus which was the real cause of cholera.

Mr. WATSON CHEYNE at the outset objected to the tone in which Dr. Klein had reviewed Koch's work. He then passed on to say that Dr. Klein's view with regard to the importation of cholera hardly explained how it was that an epidemic appeared on an island immediately after the arrival there of a patient suffering from cholera, seeing that the dejecta on Dr. Klein's showing contained merely the products of the action of the virus and none of the infective agency itself. But it was with the bacterial aspect of the subject that he specially wished to deal; and these phases of the question had to be treated. Was there a definite organism associated with cholera? Was it always present in cholera? Was it ever found anywhere else? With regard to the first point, he maintained with Koch that there was a definite organism associated with cholera; the specificity of the bacillus did not rest alone on its shape, but on the peculiarity of its mode of growth, in the way in which it grew at different temperatures, and on different substances. It was on the sum of all these characters that Koch had ventured to call the bacillus a specific one. It was to be regretted that Dr. Klein should ever have supposed that Koch meant to diagnose an organism solely on its morphological characters. Moreover, as Koch had long ago made out, the bacillus of glanders also presented the comma shape. Neither was growth in a particular manner ever regarded by Koch, or anyone else, as proving an organism to be pathogenic. The peculiarity of the method of growth merely served as a means of recognition of an organism. With regard to the second question, most observers agree that the bacillus was always present in cases of Asiatic cholera, though there were discrepancies of statements as to the numbers and site of the organisms. As to the method of estimation of numbers, if the microscope were used the number would be smaller than really existed; moreover, when growing rapidly there were fewer bacilli to be found which retained the comma shape; estimations by the method of cultivation were the only satisfactory ones. In the evacuations of an exceedingly acute case, from which Mr. Cheyne made cultivations within a quarter of an hour of their passage from the patient, he found that 95 per cent. of the organisms were comma bacilli; whereas in the dejecta themselves the comma bacilli were very few in number, but small straight bacilli were very numerous. The more acute the case the fewer comma bacilli would be found. The existence of a straight stage of the comma bacillus would probably explain a good deal of the controversy on the score of numbers. Koch had found bacilli in the intestinal wall, but neither Dr. Klein nor he had been able to find them, and he had examined two cases specially. But the comma bacilli are difficult to stain in the tissues. Koch had always found them there, but only faintly stained. Was it not possible that Koch was more efficient in the use of the methods than he or Dr. Klein? The next cardinal question was, Are the bacilli ever found anywhere else? Observers had found them in every case of Asiatic cholera that had been examined, whether in India, Egypt, Italy, France, or Spain. He had examined the saliva, evacuations, putrefying materials, and dejecta of dysentery, and had failed in every case to find the comma bacillus of Koch, or to find bacilli which in every particular agreed with the comma bacillus of Koch. The statement to the same effect made by Koch last summer was still adhered to by him. In dysentery and other diseases large numbers of comma bacilli may be found, but were they identical with Koch's? There were Finkler's, Deneke's, and Müller's comma bacilli, and he asked which one had Dr. Klein found? None of these bacilli exactly agreed with the bacilli of Koch in their mode of growth on potatoes, &c. He asked Dr. Klein in what number of cases in which it was on microscopical evidence alone, and in what number of cases it was on the mode of growth, and other characters, that he based his assertions with regard to the comma bacillus. In cholera nostras the comma bacilli did not grow in the same way as the bacillus of Koch. The bacillus found in the salivary secretions appears to be very like that of Koch, but Koch and his pupils, as well as he (Mr. Cheyne), had entirely failed to cultivate the comma bacillus from the saliva. Müller, in the *Deutsche Medizinische Wochenschrift*, had written to the same effect. This observer had found a comma bacillus in a carious tooth, which could not, however, be cultivated in the same media as those in which Koch's bacillus could be cultivated.

Dr. KLEIN interposed to say that he could not succeed if the same media were used as those which Koch used.

Mr. CHEYNE, continuing, said that that just proved his point. Dilute acids and putrefaction prevented the development of the comma bacillus of Koch. With regard to the fact that the inhabitants about the water tanks did not take the cholera, another explanation than that offered by Dr. Klein was possible: they may not have been in a condition to take the disease. Dr. Klein probably believed that the bacillus was the cause of tuberculosis and of anthrax, and yet although many individuals were exposed to the influence of the bacillus, but few became the subjects of tuberculosis or malignant pustule. As to the experiments on animals, Dr. Klein seemed to think that the positive results obtained were due to a septicæmia; in two cases out of fifteen or sixteen experiments he (Mr. Cheyne) had obtained a positive result; the symptoms during life were diarrhœa, cramps, and collapse; at the autopsy the intestines were hyperæmic, Peyer's patches were swollen, and in one of them a hæmorrhage was seen; comma-shaped bacilli were found in abundance in the contents of the intestines. It was easy to prove whether cases were due to septicæmia by making inoculations on other animals, and by examinations for the detection of an organism in the blood. All Koch's experiments on animals were conducted with complete antiseptic precautions. He considered that Koch's position had remained so far unassailable.

Dr. WARDEN gave a full account of the antiseptic precautions adopted by Koch. The abdomen was first shaven, and then carefully washed with a carbolic solution; all the water used was thoroughly boiled; the hypodermic syringe was provided with an asbestos plunger; the instruments and hands were soaked in carbolic solution. Crucial experiments were made on other animals, the only difference being that the comma bacilli were not injected. Experiments with Finkler's and Müller's bacilli yielded negative results. In a paper read before the German Board of Health Koch described small and large straight bacilli as having been found by him in cases of cholera.

Sir JOSEPH FAYRER made a few remarks, in the course of which he stated that in his opinion we were not one iota nearer the truth as to the *causa causans* of cholera, though he acknowledged his obligation to the gentlemen who had so largely contributed to the discussion.

MEDICAL SOCIETY OF LONDON.

Repair after Gangrene of Scrotum.—Choreiform Movements of Long Duration.—Etiology of Phthisis.

AN ordinary meeting of this Society was held on Monday last, Dr. W. Miller Ord, President, in the chair.

Mr. WALTER PYE showed a living specimen illustrative of the extraordinary powers of Repair after Gangrene of the

Scrotum. The patient was a man aged fifty, whose illness began with shivering, followed by inflammation about the penis; gangrene was present twenty-four hours later; in four days the gangrenous swelling burst and discharged an offensive fluid; it was at this time that the patient was first seen. There was most extensive gangrene of the penis, scrotum, and perineum, and external urethrotomy was performed. The very large slough came away on the ninth day, leaving the testes and penis bare. An abscess appeared a week later in the left iliac fossa, and this burst a week later. In the course of two months the parts exposed became completely covered by natural processes alone.—The PRESIDENT suggested that noma might have been at the root of the gangrenous condition.—Dr. SANSOM thought the case hardly presented the history which usually obtained in noma; there was none of the characteristic induration.—Mr. PYE was not certain that the disease was not one of spontaneous gangrene.

Dr. BEEVOR showed a case of Clonic Spasms of the Upper Limbs, with Anæsthesia of the Left Side, in a girl aged sixteen, who had had scarlet fever ten years ago, and six months later began to have twitching of the head and face to the left and movements in both arms. Seven years ago Dr. Barlow observed the choreiform movements affecting all the limbs. The movements have persisted ever since. A year ago the left arm was alone affected with pronation, extension of elbow, and adduction of elbow, but voluntary movements were possible; there were occasional rapid twistings of the head and both eyes to the left. Last October the right arm became affected in a similar way, and the left arm became anæsthetic and analgesic. At present the movements of the left arm were much quieter, but the limb was almost completely paralysed, anæsthetic, and analgesic. The anæsthesia also affected the whole left side of the trunk, head, and neck, as low as the level of the umbilicus; in the area of complete anæsthesia all forms of sensation were completely abolished. The face was only slightly anæsthetic; the left conjunctiva, left nostril, mouth, tongue, and fauces were deficient in sensibility. The muscular sense of weights was lost in the left arm. The sight was not affected. There was no optic neuritis. Menstruation occurred but twice a year. There was no cardiac disease. In the arms the muscles affected corresponded to those involved in Ferrier's and Yeo's experiments on the sixth and seventh cervical nerves. The case was probably of a functional or hysterical nature. The movements were irregularly rhythmical, at the rate of about sixty to eighty per minute, and ceased during sleep; though simulating chorea, they were much more regular, and affected only certain muscles; the movements of one arm were synchronous, but the two arms did not move, as a rule, at the same time. The diagnosis was supported by the character of the patient, the variation of the spasms, and the supervention of anæsthesia after so long a duration.—The PRESIDENT said that the case raised a good number of hypotheses. He suggested that during the coming year the clinical value of the deep reflexes as a means of diagnosis might be discussed with advantage. Had "transference" been tried?—Dr. HADDEN said that he had seen three very similar cases, but they came on much more rapidly; all were hysterical; the affection was like "canine chorea," which, however, ended in paralysis, and proved fatal as a rule. In the canine disease he had found areas of leucocytes around the capillaries of the spinal cord. Nerve-stretching might prove of value in Dr. Beevor's case.—Dr. BEEVOR believed that the case might spontaneously undergo rapid cure; he had not yet tried "transference."

Dr. BURNEY YEO read a paper on the Etiology of Phthisis. He said that one of the most considerable and interesting contributions to the inquiry into the etiology of phthisis that we have had of late years is to be found in Dr. Andrew's Lumleian Lectures delivered last year before the College of Physicians. He was not at one with the conclusions announced in those lectures. In admitting the bacillus of tubercle as the exciting cause of phthisis, Dr. Andrew's subsequent argument rests on the following assumption: that the bacillus of tubercle has an "independent" as well as "parasitical" phase of existence; and this assumption has borne the whole weight of the conclusion that phthisis is neither directly nor indirectly communicable! This "independent" phase of existence was no more than a pure assumption. Dr. Andrew's argument might be phrased thus: There is a bacillus of tubercle found existing as a parasite in certain men and animals; it is capable in its parasitic form of exciting phthisis in other men and animals, yet it never does so, for when it does so it is always in an "independent" phase of existence. All his (Dr. Yeo's) experience of natural phenomena led him to oppose such an argument. He considered that if one single case of phthisis has been or can be caused by an infective organism which has pre-existed in another person, the whole case of the non-contagionists is surrendered; for then the question is no longer one of communicability or non-communicability, but simply one of degree. He simply argued for the fact of communicability. He next criticised in some detail the views expressed by Dr. Douglas Powell at Belfast last year. He thought there was no evidence to support the notion that the bacilli were harmless. He believed that it was demonstrated as a fact that the bacillus of tubercle is not commonly or widely diffused even in a consumption hospital, and quoted some remarks of Dr. Hermann Weber on this subject. He narrated cases which proved to his mind that phthisis could be communicated. He quoted Dr. William Roberts to the effect that no candid person could read the report of the Collective Investigation Committee, and the detailed evidence on which it was based, without coming to these practically important conclusions: that no healthy person should be permitted to occupy the same bed with a sufferer from pulmonary consumption; that no person with an hereditary predisposition to tubercular disease should be allowed to have continued and intimate personal contact with a phthisical patient. Dr. Yeo combated at great length the arguments used by Dr. Andrew in criticising the report of the Collective Investigation Committee. He said that the appeal to clinical evidence in the present state of knowledge of the nature of pulmonary consumption could only furnish proof of the degree of communicability and the laws which govern it, and were it only one tithe of what it is, it would be sufficient to support the fact of communicability. —The PRESIDENT agreed in large measure with the conclusions contained in the paper.

OPHTHALMOLOGICAL SOCIETY.

Prevention of Blindness from Ophthalmia Neonatorum.—Nævus of Choroid.—Favus of the Upper Eyelid.—Tuberculosis of Cornea.—Evisceration of the Globe of the Eye.

A MEETING of this Society was held on the 12th inst., Mr. Jonathan Hutchinson, F.R.S., President, in the chair.

Dr. BRAILEY read the report of the special committee appointed to inquire into the Means for the Prevention of Blindness from Ophthalmia Neonatorum.

The special committee having considered the Registrar-General's letter to the Local Government Board referred to them at the last meeting, submit to the Society the following report: "That, as in the opinion of the Registrar-General, the reading over of a printed form by the registrars of births to the parents would entail a considerable expense, this may be dispensed with; and that, in place of this reading, the following notice be printed on all official documents issued to parents in relation to the birth, registration, and vaccination of children: 'If the eyelids become red and swollen, or begin to run with matter within a few days after birth, the child is to be taken without a day's delay to a doctor. The disease is very dangerous; and if not at once treated, may destroy the sight of both eyes.'"

Mr. HENRY POWER proposed and Mr. TWEEDY seconded that the deputation which already existed should be asked to wait upon the President of the Local Government Board with a view of laying before him the above recommendation of the Special Committee of the Ophthalmological Society. This motion was carried unanimously.

Mr. J. B. LAWFORD showed microscopic sections of Nævus of the Choroid. These were obtained from the left eye of a child aged eight, in whom there was an extensive capillary nævus of the same side of the face. The nævus involved the posterior part of the choroid surrounding the optic disc, and consisted of vascular channels of varying size, traversing the choroid in all directions. The retina was completely detached, stretching from the optic disc forwards to the posterior capsule of the lens. There was a large subretinal hæmorrhage. The lens was opaque and shrunken.

Mr. MCHARDY brought forward a case in which there was a rapidly extending isolated patch of Favus on the Upper Lid of a woman aged thirty-seven. It had the appearance of a

dry scabbed ulcer, and grew with great rapidity; it was excised, and the actual cautery applied. Microscopical sections and a drawing of the original disease were shown. The patient, who had completely recovered, was present.—Mr. JONATHAN HUTCHINSON said that he had seen cases of favus occurring in single patches on the skin of the body; the disease was intractable only when the scalp was affected.

Dr. C. E. BEEVOR showed a case of Opaque Nerve Fibres in a woman aged thirty-five.

Mr. W. LANG exhibited drawings of two cases of Detached Retina in the Yellow Spot Region. The patients were brother and sister; the sister was present for examination. He also showed a case of Detachment of the Retina at the Yellow Spot Region following a blow; and a third case of Central Choroiditis with Disseminated Patches in the remainder of the fundus.

Mr. STANFORD MORTON showed a case of Atrophy of the Choroid in a man aged fifty-five.

Messrs. JULER and ANDERSON CRITCHETT exhibited the case of Vesicle of the Cornea which they had shown at the December meeting. They had been unable to effect a cure, though they had tried every means known to them.—Mr. MCHARDY thought that until arsenic had been tried the case should not be regarded as incurable.

Mr. MCHARDY exhibited a man aged thirty-nine upon whom Argyll-Robertson's new operation for obstinate Ectropion of the Lower Lid, due to long-continued chronic conjunctival inflammation, was performed.

Mr. NETTLESHIP showed a case of Total Detachment of the Retina, including the yellow spot region. The affection was of several years' standing. There was practically no power of vision; even with glasses the patient could barely read 20 Jaeger.

Mr. ARTHUR BENSON read a paper on a case of Tuberculosis of Cornea and Iris. The patient was a girl aged eighteen, whose father had recently died of "decline," and whose sister was dying of the same disease. She had herself no physical signs of lung disease, but had enlarged lymphatic glands under the jaw. Two months previously the left eye, and six weeks later the right eye, became affected; greyish-yellow nodules formed in the cornea and iris, and increased in number and size. They resembled exactly the appearances seen in cases of tubercle of the iris, and in rabbits whose anterior chamber had been inoculated with lupus. The left eye was enucleated, and, microscopically examined, there were several nodules of a translucent grey colour in the substance of the cornea. They were situated external to the posterior elastic lamina, which, though extensively displaced and raised up by the masses, seemed to have resisted disintegration; the layer of endothelial cells on its aqueous surface remained intact. The neighbouring cornea was infiltrated, and its structure partly destroyed, the lamellæ being separated by masses of cell-growth. The nodules consisted of an agglomeration of round nucleated cells, in the centre of which a caseating area existed. Epitheloid cells were also abundant. In places there was an appearance as if several masses of cells had coalesced; the peripheral portions of each mass stained much better than the central. No distinct giant cells had so far been found. The nodules on the iris seemed very similar in structure. The sections prepared for detecting the specific bacilli so far yielded only negative results, but the examination had not been completed! The diagnosis was, so far, dependent upon the clinical history, the macroscopic appearances, and the anatomical peculiarities of the growth, and must therefore be left open to the possibility of error. Two inoculation experiments had failed to yield definite results. Sections of the growths, and of the inoculation growths, as well as drawings, were shown.—Mr. JESSOP asked how soon after the inoculation the rabbits were killed; whether the lungs were affected; whether any other method than that of Heneage Gibbes were used; whether any cultivations of the bacilli were made, and whether any growths were found in the choroid. He said that inoculation from pure cultivation into the anterior chamber was followed by tuberculosis of the iris and choroid as well as by general tuberculosis. So that in infection from the anterior chamber the body at large was affected, whilst in general tuberculosis of the rabbit the choroid escaped. Mr. Jessop also inquired whether the patient had any symptoms of general tuberculosis.—Mr. NETTLESHIP asked whether the growths had shrunk, and whether scraping had been practised.—Mr. J. HUTCHINSON said that he had seen cases in all respects like that of Mr. Benson's patient, with the exception that the cornea was not involved. At the suggestion of the President, a committee, composed of Mr. Jessop and Mr. Mules, was appointed to examine into the specimens submitted to the Society by Mr. Benson.—Mr. BENSON, in reply, said that one rabbit died after one week and the second one after two months; there was no tubercle in the rest of the body. Heneage Gibbes' method was the only one used. The patient showed no sign of tubercle in the system generally. No scraping had been done, and the shrinking of the untouched nodules could not be explained properly. There were enlarged glands at the angles of the jaw.

Dr. MULES (Manchester) read a paper on the Preventive Treatment of Sympathetic Ophthalmitis by Evisceration of the Globe, and the use of an Artificial Vitreous. In reviewing the history of the operation, he stated that Mülder and Græfe were working out the same operation at the same time as he was himself without any previous interchange of ideas. He pointed to the result of this new operation as a further proof of the correctness of the views advocated by Snellen, Leber, Brailey, and Max Kines, that travelling organisms were the cause of sympathetic ophthalmitis. The operation which he performed was identical with that performed by Graefe; but in addition to the operation of evisceration, Dr. Mules prepared the eviscerated globe for the application of an artificial eye, by the introduction of a hollow glass sphere or artificial vitreous, which was permanently retained; by this means the shape of the globe was maintained and very good movement obtained. The results, therefore, were æsthetically good. The operation was performed as follows. The patient was anæsthetised; the hand-spray was used, and the appendages thoroughly cleansed and disinfected with a 1 in 1000 solution of corrosive sublimate; the front of the eye was transfixed, and removed with a sharp knife at the corneo-scleral junction. He considered it better not to cut the conjunctiva. The contents of the globe were then emptied out, in any way that was convenient, taking special care to remove the ciliary body and choroid, leaving only a clean white sclera. The sublimate solution was to be allowed to run into the eye through a thin indiarubber tube, used syphon-wise, during the whole time the operation was in progress. The hand-spray was also employed as an additional precaution, and its use continued till the bleeding nearly or quite ceased. The sclera was then slit between the inferior and internal recti muscles, until the glass sphere selected would enter the cavity. A catgut drain (to be removed next morning) was introduced into the lower angle of the wound and the sclera was sewn up from above downwards. A layer of finely powdered iodoform was spread over the whole conjunctiva, and a dressing of wood-wool, in a double layer of Lister's gauze, was applied. As a precautionary measure, the patient was kept in bed for four or five days. The eye was dressed daily under the spray. If the wound were kept aseptic, the reaction was comparatively slight. If early suppuration ensued, the pain and distress were severe and prolonged. Too much stress could not be laid upon the necessity for antiseptic treatment, without which the operation should never be performed. Three sizes of artificial vitreous have been, so far, found to be sufficient.—Mr. HENRY POWER said the paper was valuable physiologically, as showing that little or no inflammation need result from the wearing of such a glass sphere; and it was valuable ophthalmologically, as showing how extremely good a stump for the application of an artificial eye could be got by thorough evisceration. He had seen Mr. Hancock perform the operation of evisceration in cases of glaucoma attended with hæmorrhage, and did not regard the operation as altogether a new one.—Mr. J. HUTCHINSON said that no doubt evisceration had not been done in a systematic manner with antiseptics, but he had not unfrequently performed evisceration intentionally, though usually more of the front of the eye was removed than was the case in Dr. Mules' patient.—Mr. CHARLES HIGGENS asked whether Dr. Mules had more evidence to show that this procedure prevented sympathetic ophthalmia.—Mr. ADAMS FROST said that a planned operation for the perfect removal of all the contents under antiseptic precautions had not been previously performed, and such an operation was very different from an accidental evisceration, where total clearing of the sclerotic was not aimed at. It remained yet to be seen whether wearing the glass sphere would give rise to any kind of irritation. Accidental breaking of the sphere was not very likely to happen; many glass eyes were broken, but not whilst they were in the orbit. He asked how long

a time the operation required for its full performance.—Mr. G. HARTRIDGE asked whether celluloid might not be tried as a material for constructing the sphere.—Mr. A. BENSON thought some irritation from the glass sphere might ensue at a late period.—Mr. JULER asked what kind of instrument was used to scrape out the globe.—Dr. MULES, in reply, said that he believed sympathetic ophthalmitis was always the result of an infective process by means of cells migrating from the diseased to the sound eye. The glass sphere had been worn for five weeks, and there was no irritation. He used about half a gallon of the solution of corrosive sublimate, and the operation lasted from fifteen to twenty minutes, including the time required to produce anæsthesia. He thought gilt aluminium would be the lightest material, but wished to try glass first, and he considered that it would not be broken; he did not think the glass sphere could get roughened on its surface. For clearing out the sclerotic dried lint rolled round a pair of forceps was used, but any device of the surgeon might be employed.

ACADEMY OF MEDICINE IN IRELAND.

AT a meeting of the Surgical Section, on January 23rd,

Mr. SWANZY read a paper on Transplantation of Skin Flaps without Pedicle for the Cure of Cicatricial Ectropia. He reviewed the steps of the proceedings as usually practised, and gave particulars of six operations he had recently performed, four of them being successful and two unsuccessful. The successful cases were exhibited. In addition to the points generally regarded as important, he drew attention to the following:—1. It is desirable that the wounded surface on the eyelid should be made as extensive as possible by the dissection of the everted lid being carried to the fullest extent. It is not sufficient, as usually recommended, to carry the dissection only so far as to bring the free margin of the eyelid being operated on in contact with the free margin of its fellow, but the dissection of the lid from the surface underneath to which it is attached should be gone on with until, on reflection, the free margin reaches up to or beyond the eyebrow, if it be the lower lid, or as far as or below the infra-orbital margin, if it be the upper lid. The object of this is to provide for the inevitable shrinking which takes place in the transplanted flap, so that the ultimate size of the eyelid may not be less, or much less, than normal. This second point had not before been mentioned. 2. With regard to securing the flap in its new position by sutures, it would be much better if sutures could be done without, as they cause suppuration at each point. The author had no experience of Wolfe's method of securing the flap without sutures. If sutures are used, they should be of fine silk or of fine platinum wire, and only so many as suffice to keep the flap in its place. Catgut sutures are not suitable, as they do not hold long enough to enable the flap to become adherent. A large number of sutures is unnecessary, and causes a line of suppuration around the margin of the flap, but platinum wire seems to cause little suppuration. 3. With regard to the dressing, carbolic acid should not be used in any form, being apt to irritate the delicate skin flap and increase the liability to peeling of the epidermis. He did not agree with Wolfe that the "so-called antisepticism" has no place in ophthalmic surgery. In this proceeding the dressings should be antiseptic, but they should be also non-irritating. Boracic acid and sero-sublimate were among the suitable applications. Finally, the author pointed out that where the epidermis has not peeled the shrinking is slight in comparison with where it comes away, and where the rete Malpighii has to throw out a new cuticle.—Dr. BENSON said that at the late Surgical Society he had himself read a paper on the same subject, giving the results of eight cases of transplantation from the arms to the eyelids without pedicle, and with a tolerably fair average of success, though not so large as Mr. Swanzy had. As to the failures, he asked if the lid was made better by the operation, even though the flap sloughed. He also inquired as to the time of the return of sensation in the transplanted skin. The use of carbolic acid as a dressing he condemned, the effect being to irritate the wound; he preferred vaseline.—Mr. WHEELER observed that in the formation of new noses, where the flap was taken from the forehead, sensation returned earlier than when taken from the cheeks or by Syme's operation.—Mr. STORY remarked that all the nerves had to do when the flap was taken from the forehead was to continue growing in order to restore sensibility; but when the skin was transplanted *en masse* from the arm without pedicle, the new nerves had to join on to the skin beneath, and therefore the early return of sensibility was not to be expected. — Mr. SWANZY, in reply, was mindful that Dr. Benson had anticipated him in the operation. His experience of it was extremely favourable. Of seven cases, two had been complete failures, while the rest were, surgically and therapeutically, complete successes. The two failures occurred in the same patient, and arose from the untimely melting away of the sutures. As a rule the epidermis came away, but he did not desire that result, the flap not being unlike the skin of the cheek when it remained, and the tissue underneath had not to go through the granulating process. He did not note the return of sensation, but it did not take place in less than a week or a fortnight.

Mr. STOKES read a paper on Astragaloid Osteotomy in the treatment of Flat-foot; and Mr. KENDAL FRANKS read a paper on the Treatment of Flat-foot by Ogston's Operation. The discussion on both papers was postponed to the next meeting.

MIDLAND MEDICAL SOCIETY.

AN ordinary meeting of this Society was held on the 4th inst., the President, Mr. T. H. Bartleet, in the chair.

Dr. THOMAS showed a patient on whom he had resected about an inch from the centre of the shafts of the left radius and ulna, to remedy severe Angular Ankylosis of the Wrist. The bones of the forearm had been fractured in 1881, and during the treatment a deep slough formed on the posterior aspect, leaving a cicatrix about two inches in length closely adherent to the bones. The wrist was firmly ankylosed in a position of acute flexion, and the use of the arm further impaired by an unreduced dislocation at the elbow. The cicatrix was dissected away, and about an inch of the bones removed. It was found that the wrist deformity was very little affected immediately, though considerable improvement ultimately followed. The ends of the two bones were placed together, the corresponding periosteum being united by fine catgut sutures. Considerable opening out of the angle of the wrist was secured, so that the arm was much more useful than before.

Mr. JORDAN LLOYD showed a Tumour which had grown in the breast of a girl, aged nineteen, within a period of eight months. The tumour was movable in all directions; at times painful and rapidly growing. The skin was full and traversed by large veins, the glands in the axilla enlarged. The whole breast was excised, the skin plentifully sacrificed, and the axilla thoroughly cleaned out. The patient has done well since. Microscopic sections were shown, the growth being an adeno-sarcoma.

Dr. SUCKLING exhibited Squibb's Apparatus for the Estimation of Urea, and recommended it as being cheap, portable, and accurate. He also showed a case of Cerebral Syphilis. The patient, a woman aged thirty, had had two miscarriages. Last December she was taken ill with severe pains in the head, vomiting, and vertigo, and was confined to bed for three weeks. She attended the Queen's Hospital as an out-patient in February, and had been treated with iodide of potassium in increasing doses. There were paresis of the right side, with increase of the deep reflexes, paralysis of the right third nerve, and peripheral paralysis of the left facial nerve, "the reaction of degeneration" being well marked. The speaker pointed out the multiplicity of the paralyses as being very characteristic of syphilis, and indicated the probable situation of the growths. There was no optic neuritis. The hemiplegia and paralysis of the third nerve were improving rapidly under the administration of thirty-five-grain doses of iodide of potassium thrice daily; but the facial paralysis remained unaffected. Dr. Suckling further showed a case of Peripheral Monoplegia in an infant of five months; the paralysis dated from birth, great difficulty being met with in delivering the shoulder. There were anæsthesia and contracture. The reaction of degeneration was present in a severe degree. He believed the accident to be a very common one, and urged the necessity of immediate treatment.

Dr. PURSLOW showed a specimen of Spontaneous Rupture of the Œsophagus into the Right Pleural Cavity, from an infant aged eleven months. There was no appearance of ulceration in the wall of the stomach or œsophagus, and no trace of a foreign body. The child was admitted with bronchitis twelve hours before death, and the fatal termi-

nation was sudden and unexpected, and preceded by convulsions.

Mr. EALES read a paper on Concomitant Internal Strabismus, and drew attention to its being almost invariably associated with hypermetropia. He then explained the mode in which the defect in focus brought about the squint; and having alluded to astigmatism and certain other conditions causing defective vision in one eye, pointed out how monocular defect contributes in a large degree to the occurrence of strabismus. He maintained that the essential cause was the hypermetropia, and that most cases if taken in time might be cured without operation by wearing suitable glasses. He thought operation should not be resorted to till glasses had failed to cure the squinting, and considered them necessary adjuncts in the after-treatment. He thought that the cure of squint by atropine drops without the aid of glasses was most improper, as the patient's vision was then bad for both distant and near objects. He had in a few cases cured squint by eserine drops, but found the result to be very rare. He thought this method of treatment only worth a trial in children too young to wear glasses.

WOLVERHAMPTON DISTRICT MEDICAL SOCIETY.

A MEETING of the above Society was held in the Bell Library, Wolverhampton, on March 5th, the President, Dr. Ballenden, in the chair.

Mr. VINCENT JACKSON showed two children lately operated upon for the Radical Cure of a severe form of Inguinal Hernia. The operation consisted in ligaturing and excising the sac, and closing the external ring with silver-wire sutures. No truss had been worn since the operation, and its curative character had been well tested, as each child had been a sufferer from whooping-cough since its performance.

Mr. VINCENT JACKSON also showed a Tongue removed on account of an Epithelial Cancer of the left side, the point of interest being the fact that, although the excision was performed slowly with the chain écraseur, yet, upon detachment, both lingual arteries required ligaturing.

Mr. CROCKETT then continued the discussion adjourned from the last meeting by reading a paper on Puerperal Fever, which, after alluding to the varied nomenclature and treatment, he divided into the three varieties of "inflammatory," "sapræmic," and "septicæmic," and subdivided all cases into autogenetic and heterogenetic. As to treatment, he strongly insisted on thorough antiseptic precautions, and thought the hyposulphites promised to be useful.—The debate was continued by the chairman, Drs. Totherick and S. Smith, and Messrs. Newnham, Jackson, and Magrane.

Dr. LYCETT then exhibited an instrument for facilitating the Radical Cure in Pyo-pneumothorax, and also an instrument for Dilating the Cervix Uteri.

CARDIFF MEDICAL SOCIETY.

The Measles Epidemic.

AT a meeting of the above Society, held at the Infirmary on the 11th ult., a discussion took place, in which the following members took part:—Mr. C. E. Hardyman (President), Dr. Campbell, Dr. M. G. Evans, Mr. A. Blain, M.B., Mr. W. H. Greener, M.B., and Mr. T. Garrett Horder (Hon. Sec.). The principal facts enunciated were:—1. That the deaths were in a large number of instances caused by pneumonia and broncho-pneumonia, and that these affections were rapidly fatal in the families of poor people. 2. That the epidemic was most fatal in the districts of Grangetown and South Splotlands. 3. That the cases in parts of the Cardiff district, especially in that part called Cathays, were of a mild nature. 4. That in three instances at least children were known to have passed through two distinct attacks within a month. 5. That many children suffered from gangrenous affections of the mouth and skin. It was pointed out that when the epidemic commenced the weather was very cold, the wind being easterly or north-easterly. It was also pointed out that in Grangetown (where the epidemic was most fatal) very bad smells had been noticed since the flooding of the district; and it was suggested as being probable that the main sewers had become disconnected by the force of the flood, and had caused the sewage to flow under the basements of the houses. The deaths recorded from this epidemic from Oct. 25th, 1884, to Jan. 24th, 1885, were as follows:—Grangetown, 55; Canton, 15; Cardiff, 33; Roath, 50—total, 155.

Reviews and Notices of Books.

Syphilis and Pseudo-Syphilis. By ALFRED COOPER, F.R.C.S. London: J. & A. Churchill, 1884.

THE literature of syphilis appears to keep pace even with the rapidly increasing number of affections which are attributed to the disease. Besides the large work by Bumstead and Taylor, and the recent enlarged edition of Berkeley Hill's treatise, we are now presented with the results of Mr. Cooper's large experience in private and hospital practice in this department. The work commences with an interesting inquiry into the history and the geographical distribution of syphilitic affections. The author then reviews at some length the relationship between the hard and the soft sore. He agrees with most of the authorities in this country that the poison of the hard chancre is a "specific virus, a pathological agent separate and distinct from every other animal poison." But he declines to attribute to the soft chancre any specific character whatever, believing that such an ulcer may "arise *de novo* from inoculation of the products of inflammation." We cannot, however, regard the evidence adduced by the author as conclusive of this theory. This evidence mainly consists in the fact that pustules of various sorts, such as acne, contain a discharge which, if inoculated, is capable of producing a similar lesion to that from which it was itself derived. While not denying this, which indeed is a matter of everyday observation, in the case of boils, &c., we cannot admit that this excludes the possibility of a soft chancre being due to some specific poison. It does not follow, because matter from an ordinary pustule can reproduce a similar pustule, that an ulcer has no specific characters because its discharge is capable of doing the same, and the uniform course and duration of the soft chancre which Mr. Cooper describes point to the sore being the result of some special poison. We are surprised that the author, who insists that a soft chancre is nothing more than a pustule resulting from irritating secretions, should give it the name of "pseudo-syphilis."

In subsequent sections the various forms of eruptions on cutaneous and mucous surfaces are described with much care and minuteness, and a considerable space is devoted to Diseases of the Eye, this chapter having been subjected to the criticism of Mr. Anderson Critchett. The nervous lesions due to syphilis are those especially on which our knowledge of late has increased, and here Mr. Cooper has secured the advantage of revision by Dr. Buzzard.

The chapter on Hereditary Syphilis describes in much detail the pathological alterations found in the bones and other tissues, but we would suggest that in future editions some separation between clinical appearances and anatomical appearances should be made. Mr. Cooper raises an able protest against the abolition of the compulsory clauses of the Contagious Diseases Acts, and quotes the authority of Mr. Parker Wilson, Surgeon to H.M. Military Prison, Brixton, that already as a result not only is the number of cases of syphilis increasing, but "the character of the disease, which had become modified, is beginning to assume its old virulent type." Under "Prognosis in Syphilis" Mr. Cooper asserts that rupial ulcerations in an early stage are likely to be followed by severe cerebral symptoms, but he is evidently of opinion that the actual prognosis in most cases depends on the care and discretion with which mercurial treatment is carried out.

Valuable information is given as to the treatment of the

various symptoms, and Mr. Cooper especially insists on the baneful effects of alcohol in syphilitic patients. The work is an instructive and comprehensive treatise on the effects of syphilis, comprising the latest information on the subject, and it will doubtless not disappoint the author in his expressed hope that it may be of service to practitioners and to students.

Practical Pathology; a Manual for Students and Practitioners. By G. SIMS WOODHEAD, M.D., F.R.C.P. Edin. Second Edition. Edinburgh: Young J. Pentland. 1885.

THE comparatively brief interval that has elapsed since the publication of the first edition of this book shows that its merits have been well appreciated, for it occupies almost a unique position, and constitutes a thoroughly trustworthy guide in pathological research, which might well be made the basis of class instruction. The student has now so many excellent treatises on pathology to select from that his choice must often be an embarrassing one; but if he were limited to one book he would do wisely to select that which furnishes him with instruction how to investigate morbid tissues for himself, for the knowledge thereby gained is that which is the most enduring. To our thinking the ideal plan of pathological teaching is that which enables the student to see, handle, and prepare the specimens for himself, added to an exposition of their characters, and preceded by a general disquisition on the broad principles of pathology. In this, as in other departments of medical education, the most value is derived from the practical work which supplements the theoretical matter derived from reading and systematic lectures. Dr. Woodhead has submitted his book to careful revision, and amongst the most important additions is a chapter on the Female Organs of Generation, contributed by Mr. Milne Chapman, M.B. We confess we should like to have seen this chapter dealing more in detail with uterine cancer than it does; and we should be disposed to question the statement that the commonest variety of such malignant disease is a true carcinoma, although there can be no question of its being a form of "diffuse-infiltration" growth. The highly interesting subject of ovarian new growths and cysts is also too cursorily dealt with. In other sections there still remain deficiencies, which will doubtless be supplied in future editions, notably in the chapter on the Nervous System; and as there still remain organs not yet included in the treatise, we may look forward to the gradual evolution of a work which shall be well nigh exhaustive of the subjects. The number of the illustrations, which, it may be remembered, are coloured so as to reproduce the appearances of the stained preparations from which they were drawn, has been increased, and we notice that some of those present in the earlier edition have been replaced by others more characteristic of the lesions represented. It is not difficult to predict for the book an enduring success.

SANITARY CONDITION OF CALCUTTA.

THE mixed committee which was appointed by the Lieutenant-Governor of Bengal in September last to inquire into the alleged defective nature of the arrangements for the cleansing and conservancy of Calcutta, and to report as to what further provision should be made for this important duty, have submitted their report to the local Government. It has not yet reached us, but judging from the copious extracts given in the *Calcutta Englishman*, the committee appear to have examined the subject carefully and impartially, and, while pointing out the defects, give the municipal sanitary commissioners full credit for the improvements they have already introduced. The committee made frequent examinations of the sewers, and heard all the evidence brought before them. The conclusions at which they arrived with regard to the main sewers were that, although there has been a marked change for the better in their condition since the increase of the conservancy establishment in 1883, there is still considerable room for improvement; but they think that before any expense is incurred in the way of erecting flushing tanks or reservoirs, it would be advisable to wait to see the effect which the extension of the waterworks will have on the sewers. At the same time they point out the importance of keeping a sufficient establishment to remove by hand the deposit which, even with increased flushing power, can scarcely fail to take place. As regards the second-class brick sewers, they say that they act fairly well, but in the dry season "they depend for their sweetness entirely upon the quantity and character of the sewage brought down by the pipe sewers; and it cannot be said that at present the flushing of the pipe sewers affects to any appreciable extent the removal of deposit from the brick sewers." The pipe sewers are stated to be in a very unsatisfactory condition, and the means of cleaning them inadequate, and the committee recommend the provision of greater facilities for flushing. They express an opinion that none of these pipe sewers should be left more than a month without being examined, and doubt whether the existing establishment is sufficient to carry out this duty efficiently. The difficult and important question of the ventilation of the sewers was carefully considered, and although no recommendation on the subject has been made, the committee acknowledge the objection to the system of gratings opening at the street level, and appear to favour the erection of pipes connected with the sewers and carried well above the roofs of the houses, which the commissioners are authorised by the Act to do. With regard to the estimate for the year 1885-86, which they were to submit, the committee report that they have found great difficulty in coming to a conclusion. They are of opinion that the work of filling up foul tanks should be proceeded with as quickly as possible, but that the order in which these should be taken must be left to the decision of the commissioners and the executive. While giving the commissioners credit for the very able manner in which they have managed their financial affairs, the committee express the opinion that the expenditure for the cleansing and conservancy of the town has not been on a scale commensurate with its requirements, and that the representations of the executive have not been treated with the consideration they deserve. They point out, in fact, that there has been "a tendency on the part of the commissioners to regulate their expenditure so as to keep down taxation without paying sufficient regard to the actual requirements of the town." And again they remark, "When we find the executive, year after year, asking for increased establishments and appliances to work with, and when we ourselves find that, with the existing machinery, the work is not satisfactorily performed, we cannot help thinking that the sanitary requirements of the town have been sacrificed to the desire to maintain the house rate at 7½ per cent." The committee bring under notice the necessity, in the interests of the town, for extending to the suburbs the sanitary measures which are necessary to bring them into a satisfactory health condition. "The town can never hope to enjoy a low death-rate so long as it is surrounded on three sides by an insanitary tract like the suburbs." The report concludes with a summary of the recommendations made by the committee as to improved drainage, increased water-supply, filling up of foul tanks and wells, the provision of additional bathing platforms, improvement of public latrines, increased establishment for road cleaning and conservancy, putting the registration of births and deaths more directly under the control of the health officer, and placing the suburbs under the same municipal administration as the town. The report of the committee, so far as we can judge from the extracts which have reached us, appears to show that in the agitation which was got up in Calcutta on the subject, sufficient credit was scarcely given to the municipal corporation for the sanitary improvements they had effected, but it also fully justifies the course adopted by Sir Rivers Thompson in instituting a searching inquiry into the complaints made of serious existing defects. We sincerely trust the labour the committee have bestowed upon it may not be thrown away, but that the municipal commissioners will co-operate cordially with the executive in carrying out, with as little delay as possible, the sanitary measures which have been recommended, and in extending them to the suburbs.

THE LANCET.

LONDON: SATURDAY, MARCH 28, 1885.

RARELY has the Royal Medical and Chirurgical Society been the scene of so large a gathering as that which took place last Tuesday, on the occasion of the first night's debate upon Cholera; and certainly those who attended the meeting were well rewarded, for at length the profession had the opportunity of hearing the statements of those who have been actively engaged in the study of the bacterial organisms associated with the disease, and of witnessing on a lavish scale microscopical preparations and cultivations in various media of the lengthening list of comma-shaped organisms which have been brought to light since KOCH first discovered a similar microbe in Asiatic cholera. These preparations were shown by Professor WARDEN of Calcutta, who has recently spent some months working under Dr. KOCH'S direction at Berlin, by Drs. KLEIN and GIBBES, Mr. WATSON CHEYNE, Dr. HERON, and others, the whole furnishing a demonstration which was alone worth the visit. As for the debate itself, interesting as was the exposition of his views given by the President, of far greater interest were the speeches of Dr. KLEIN and Mr. WATSON CHEYNE, presenting as they did the two aspects of the question which has for so many months agitated the scientific world. It is much to be regretted that the limited time at the disposal of the Society did not allow of an extension of the debate upon this particular point, for although the subject is to be continued at an extra meeting, it was intimated that on that occasion discussion will be mainly directed to the general pathological and therapeutical questions, as raised by Dr. JOHNSON.

The President's opening paper was a clear and well-reasoned argument in favour of the doctrine that the choleraic virus has its seat in the intestine, and that the choleraic collapse is due to obstructed pulmonary circulation from arterial spasm excited by the action of the poison. This theoretical consideration was supported by a plenitude of reasoning from experimental physiology and pathology. Upon this view, which regards the alvine discharges as more or less critical, and the channel whereby the poison is eliminated, is based the notion that the best means of treatment is an early evacuation of the bowels before the poison is absorbed; whilst measures, such as opiates, to arrest the discharges are harmful. Dr. JOHNSON has long advocated these views, but it is well that they should again be laid before the profession, which requires, in spite of the experience of half a century, to be instructed upon the most rational treatment to be pursued. It is not unlikely that in the coming months opportunity will be offered for this, and in initiating a debate upon the subject the Royal Medical and Chirurgical Society is doing a work which will be much appreciated.

But, as we have indicated, the leading feature of the evening was the speech of Dr. KLEIN and the criticism passed upon it by Mr. WATSON CHEYNE; and it was to illustrate this portion of the subject that the remarkable demonstrations referred to were devoted. The conclusions arrived at by Dr. KLEIN and his colleague, Dr. HENEAGE GIBBES, have already been fully laid before our readers, but hitherto they have passed without challenge. Dr. KOCH has not himself replied to these statements, but his position was fully represented by Mr. CHEYNE, who studied the subject during the recent epidemic in Paris. Dr. KLEIN took great pains to show, in his opening remarks, that the choleraic virus could not be of the same nature as that of such infectious diseases as tubercle or anthrax; depending, that is, upon a micro-organism which penetrated the blood and was reproduced throughout the body. He pointed out the facts telling against the contagionist doctrine, which Dr. JOHNSON had just previously said could not be denied, and even went so far as to state that the virus was not contained in the excreta. The position which he holds is much the same as that of PETTENKOFER, who seeks in conditions external to the human body for the source of the virus. No doubt we shall hear a very great deal more upon this point, which has so long been contested, and upon which so many arguments may be adduced on either side. Were it not for the fact that many physicians concur with Dr. JOHNSON in the contagionist doctrine and the infective character of the excreta—in other words, were Dr. KLEIN'S position accepted as beyond dispute, then there would be no justification at all for elaborate search for the contagium in the alimentary canal. If Dr. KLEIN held these views before undertaking his research in India, he must have been influenced by them, and could hardly have approached his investigation in an unprejudiced spirit. Apart from this, there remain questions of fact which are in dispute, and these ought to admit of settlement. First, there is the question as to the invariable presence of the curved bacilli in the choleraic discharges and intestinal contents. Dr. KLEIN admits so much, but is unable to corroborate KOCH'S assertion that in the acuter cases and soon after death the lower ileum contains these bacilli in remarkable abundance. Dr. KLEIN found just the reverse, and asserts that the nearer to the time of death that the examination is made the sparser are the bacilli; but he adds that even more constant were small straight bacilli in the mucous flakes. Mr. WATSON CHEYNE'S reply to this was that KOCH'S statement did not rest upon the morphological criteria alone; it was based on the fact of cultures, which showed that in such cases the ileum contains hardly any other species of bacterium. And Mr. CHEYNE had not only confirmed this himself, but could also confirm Dr. KLEIN'S statement as to the paucity of curved bacilli and the number of straight forms. The fact is, much misconception appears to have arisen from the adoption of the phrase "comma-shaped," for it appears that the curving is but an incident of one stage in the life of the bacillus, which, whatever its morphological changes, exhibits invariably the same reactions and characters on cultivation. Dr. KOCH and Mr. WATSON CHEYNE are positive upon this point. No other bacterium known to them, be it comma-shaped or not, can exhibit the same characters when cultivated. It is a distinct species. But Dr. KLEIN showed gelatine cultures of the mouth-bacillus (of MÜLLER and LEWIS) which were indistinguish-

able from those of the choleraic organism. Mr. CHEYNE stated that he and others had repeatedly tried to cultivate the mouth-bacillus in the same media as KOCH'S organism, and failed; and he inferred that Dr. KLEIN'S cultures must have been in different media. The acknowledgment that this was the case was most significant; for, small as the point may be, it suffices to show that there *is* a specific difference between the two comma-shaped organisms, just as they each differ from the bacillus of FINKLER and that of DENEKE. Another striking point of divergence arose upon the subject of transmission of cholera to the lower animals. Dr. KLEIN was justified in ridiculing the original experiments of NICATI and RIETSCH, for the preliminary ligature of the bile-duct they deemed necessary before injecting cultures of the comma bacillus into the duodenum. That procedure, which much complicated the issue, was unneeded, and was abandoned; and some successful inoculations have been practised by KOCH, WATSON CHEYNE, and others. Dr. KLEIN never succeeded, and attributed the results of others to septicæmia, forgetting, as Mr. CHEYNE and Dr. WARDEN reminded the meeting, that of all men KOCH is the most likely not only to recognise septicæmia when he meets with it, but to take suitable precautions against the possibility of such a mischance occurring. Space will not permit us to follow other matters, such as the absence of any gross anatomical lesions in the intestine according to Dr. KLEIN, and the swollen and injected condition of Peyer's glands invariably found by Dr. KOCH; nor the question as to the penetration of the mucosa by the bacilli, which Dr. KLEIN never saw, but which is shown in Dr. KOCH'S preparations, and is attributed by Mr. CHEYNE to the latter's skill in staining them. Nor need we do more than refer to the instance of the now famous tank visited by both Dr. KOCH and Dr. KLEIN, but under very different conditions as regards the prevalence of cholera in the vicinity, and the naturally divergent inferences drawn by each in consequence.

It is at any rate satisfactory that the results of Dr. KLEIN'S Commission, which were so opposite to those of Dr. KOCH'S, should at length have been submitted to the criticism of those who have come to the same conclusions as the latter; and it surely is not difficult to harmonise the two to this extent—viz., that the choleraic intestine does contain invariably a microbe of special and peculiar properties, which appears to go through many changes in form in its development—straight, curved, spiral, &c.; but which is perfectly distinct from any other known species of microbe. To Dr. KOCH remains the credit of demonstrating this fact; and Dr. KLEIN'S investigations, when read by the light of reason, may be held to confirm it also. But, singular as this fact is, are we justified in assuming that this microbe is specific and pathogenic? Here Dr. KLEIN'S criticisms upon the nature of the choleraic virus deserve more attention than they have received; and we imagine that at present the verdict must be one of "not proven." For it is remarkable how meagre is the evidence which connects this choleraic organism with the origin of the disease itself. It may yet be that by a closer imitation of the conditions under which cholera is transmitted (for, *pace* Dr. KLEIN, we cannot doubt that it is directly communicable) this crucial point will be satisfactorily determined. If it were established beyond dispute, the task would still remain to harmonise the other abundant and discordant facts concerning the disease which have accumulated in the history of epidemics with the new doctrine, which Dr. KOCH himself does not hesitate to adopt.

THE Hospitals Association was well occupied on the 18th instant in hearing a paper by Dr. BRISTOWE on the out-patient question, including the subject of provident dispensaries. This subject has been very much discussed. A large amount of sense and a still larger amount of nonsense have been talked about it. Lately, in accordance with the spirit of criticism which is abroad, everything in the old-fashioned administration of our medical charities has been questioned, a disposition has been shown to add to the torture of sickness that of a severe inquiry into social circumstances, and to convert hospitals and dispensaries, in which needy and sickly people have been in the habit of finding medical help on charitable terms, into petty shops in which, on low commercial terms, whosoever pleased may find all the resources of surgery, physic, and pharmacy. This tendency will be most beneficially checked by the address of Dr. BRISTOWE, which should be carefully read by every person interested in the dignity of medicine and in the welfare of the sick poor. It shows the really complicated nature of the questions involved in any attempt seriously to curtail the proportions of the out-patient departments of hospitals, or to commercialise the terms on which patients are relieved in our medical charities. It takes a true physician to make such a statement as that of Dr. BRISTOWE. The definition of poverty, or rather the demonstration of the impossibility of defining it; the inadequacy of a mere wage or income test of it; the delicate appreciation of what we may call refined poverty, the poverty of those who have known better days, or whose means are hopelessly disproportionate to their necessities or their necessary appearance in society; the striking account of the amount of grave disease treated in hospitals—are all features in the address which should make the advocates of wholesale change in our public medical institutions pause. It has been too much the fashion of those who dislike the out-patient department of hospital work to represent the diseases treated as trivial and fanciful. Fanciful disease does not much frequent hospitals. Dr. BRISTOWE is nearer the mark in showing how people "suffering from chronic, incurable, or obscure disease gravitate towards a hospital"; "those with heart disease, chronic renal disease, bronchitis and chronic forms of phthisis, chronic diseases of the liver, abdominal tumours and uterine disorders, dyspeptics, the epileptic and the hysterical," &c. We cannot even afford room for the list; but it represents a great mass of suffering, which is borne with wonderful patience and absence of complaint, and which in the rich would be met with the wisdom of a dozen consultants and with the virtue of as many different climates. These are not the days for weakening the human and sympathetic bonds which have long existed between the different classes of society—classes to which, on the one hand, it has been so pleasant to give help, and on the other so convenient to receive it.

We are glad to see that Dr. BRISTOWE demolished that "million" that is so loosely said to "sponge" on the medical

charities of London, not from any actual disease, but just for the pleasure of taking cheap physic. With no wish to see unfit cases treated at hospitals or dispensaries, and without denying that there are not a few such, we have often protested against this coarse statistic as a thing that would not bear examination. Dr. BRISTOWE shows how one and the same chronic sufferer figures as a new patient each time he changes his letter; how he goes through the same process in other institutions; and how, even in the same hospital, he may be under treatment in two different departments. By such means he carries the reduction of the million to one or two hundred thousand. This is a bolder reduction than even we have ventured to make; but there is much truth in it, which we venture to recommend to Mr. FREWEN of the Hospital Saturday Fund, who since Dr. BRISTOWE's address has enlarged the million to one million and a quarter in an address on Metropolitan Hospital Reform, and whose sole idea of hospital reform seems to be that all hospitals should reduce their expenditure per bed to 25*s.* per week.

Dr. BRISTOWE expressed great objections to payments by patients in hospitals, especially in their tendency to lead the poor to think that they were actually buying medical advice and medicines, and thus to put hospitals into a kind of competition with private practitioners. Dr. BRISTOWE spoke in similar tones of the tendency of Provident Dispensaries, or at least of those that aim at supplying medical treatment and medicines "at unremunerative prices." This has been the tendency of the metropolitan provident dispensaries, and *a fortiori* of those Provincial Medical Associations which aim at breaking up the family doctor relation of the practitioner to the working classes, and exacting an enormous amount of work for a mere pittance. Better far retain our medical charities for generous and not too critical use in the emergencies of life, or by the afflicted members of humbler families, and leave these very families to pay what they can to their ordinary trusted adviser—generally a larger sum, we venture to say, than is paid under the much-vaunted provident dispensary system, which has done much to lower the estimate of medical service. We cannot prolong our notice of this admirable paper of Dr. BRISTOWE, even to dwell on that part of it which shows the enormous educational advantages of the existing hospital system. But we hope we have said enough to encourage our readers to give it careful perusal. It is gratifying to be able to add that many members present expressed concurrence with Dr. BRISTOWE's views.

EARL GRANVILLE'S circular letter to the British ambassadors abroad, calling for reports on the laws relating to lunatics in force in other countries, must be accepted as evidence of a desire on the part of the Government to amend the laws of our own land in the light thrown on the subject of insanity in its socio-legal aspects by the lessons to be learned from the practice of contemporary nationalities. If this be the temper of the Legislature as well as of the executive, there is one lesson—and we hold it to be most important—which stands out so conspicuously that it cannot be disregarded. We allude to the precautions taken by nearly every State except our own to ensure the identification of each person alleged to be insane, and to prevent the individuality of the case from being lost. If only this advantage could be secured for the victims of "certifying" in this country, a great step would be taken on the road to reform, and a very considerable, if not practically all-sufficient, safeguard for the sane would be gained. The initial fault and the crying evil of the lunacy system in operation in this country lie in the fact that whereas certificates of lunacy actually deprive the person named in them of his civil rights, they do not so specialise his case that it can be—or we would prefer to say must be—kept under official observation, *in the interests of the person alleged to be insane*, with a view to the instant detection of any error which may have been made in the necessarily hasty judgment formed by his medical examiners, or the restitution, immediately on recovery, of the rights and privileges of which he has been deprived. It is simply intolerable that because a man happens to have some disturbance of the functions of the cerebrum, perhaps of quite a temporary nature, he should be deprived of that self-control and self-respect which are the most cherished attributes of the human consciousness, and placed in the position of a cowed creature held in bondage by those around, a slave in every mental sense, to the sore wounding and chafing of soul and conscience, and to the lasting detriment of the whole moral nature. It is a grievous pity that any consideration should be thought to make such a degradation of the man sick in mind needful; but, if it must be so, clearly it is incumbent upon us to see that when and where this humiliation is imposed its subject or victim may not for a single instant be permitted to pass out of the field of vision. When and while NEBUCHADNEZZAR is compelled to eat straw like an ox, at least let some thoroughly impartial person be set over him to see that he is really mad, and to lead him back to the ways of humanity the instant his reason is restored.

The precautions taken in foreign countries to make sure that the alleged victims of insanity are really insane are better than those nominal measures held to suffice at home. In Austria "official sanitary authorities must study the history of the malady of each patient." This is part of the bounden duty of the inspectors of asylums. Imagine for one moment the consternation likely to be produced at our Board of Commissioners if such a rule were to be enforced here! In France "in the case of private asylums, the Prefect shall send within three days [of the admission of a patient] one or more experienced men to report upon the case." In Germany "a patient cannot be confined at the request of a private person, not even if such person be a parent, husband, or wife (as the case may be) in any asylum, public or private, but only at the request of the court or of the local police authorities." We in England care nothing who makes the request; it may be any man hired out of the street for a couple of shillings, or the most dire personal enemy of the person to be confined, perhaps one who can work vengeance or make profit by getting the subject of the "order," or request, out of the way and deprived of his civil status and powers, though it be only for a brief period. And in Germany, if wrong be done in this way, there is no such thing as mere sueing for damages; but the doer of the wrong is punishable with hard labour up to ten years, if the "deprivation of freedom last over one week." In Italy the medical certificate requires the

affidavits of "two witnesses," or "a decree of the judicial authorities," to make it valid. In the Netherlands "authorisation for the admission of a patient into a lunatic asylum must be applied for in writing to the judge of the court of the district in which the patient resides by one of his relatives or his guardians, or, in their default, by the officer or justice of the said court.....It is only on the exhibition of the authorisation in question that any person can be admitted—and this only provisionally—as a patient in an asylum." In Portugal "a lunatic is admitted to the asylum in virtue of a judicial decree on the demand of the administrative authorities," and "the examination of the lunatic by the certifying physician must take place in the presence of a judge and witnesses." In Russia, unless there has been an official examination before the admission of a patient to an asylum, "the Governor [of the province] shall immediately ascertain—in a private manner and without publicity—whether, in placing the person therein, there has been any abuse of power," &c., and "at the examination of insane persons, whether at the seat of the county or local administration, the Governor shall preside over the proceedings in person."

All this shows how careful the Governments of other States are to protect the insane and to prevent malpractices. If we compare our method with that of almost every other civilised people we must see how deplorably we fall short in the discharge of a great public duty. In Sweden and Norway the medical examiner is not left without express guidance as to the mode of his examination, and so full and precise are the details to be furnished by him, that it is scarcely possible that in the absence of intentional fraud an error can be committed. In the United States of America there is a strangé want of uniformity in the law and practice; but in some States—for example, Massachusetts—"no person can be committed to a lunatic asylum except by a judge's order." While side by side with this excellent provision "the superintendent [of an asylum] is allowed to receive and treat any person as a boarder and patient who is willing to undergo treatment, but whose case is not sufficiently serious for a physician's certificate," thus supplying a much-needed facility for the prompt aid of the large class of patients not yet actually insane, but in danger of becoming so—a class for which, in England at least, we make no provision, and practically refuse to help in the self-conscious stage of their malady.

Whatever else may come of the lunacy reform undertaken by Her Majesty's Ministers, we trust that the first great lesson to be learnt by the reference of the Foreign Secretary to the laws and practice of other nations will not be unheeded.

THE subject of the Croonian Lectures, just delivered at the Royal College of Physicians, is one of the highest practical importance, and it could have received few exponents better qualified to deal with it than Dr. HERMANN WEBER. The time has happily gone by when pulmonary phthisis was regarded as a hopelessly incurable disease, but such teaching as Dr. WEBER'S is needed to enforce not merely the truth of its curability, but of the possibility of its prevention. In this country especially, where consumption claims so many victims, it is imperatively necessary to listen to such doctrine, and to spare no effort to follow the lines indicated for the prevention of this scourge. The task is beset with difficulties, but they are not insuperable, for were the sums now freely expended in the waging of wars, the ultimate advantage of which by no means counterbalances the sacrifices endured, devoted to measures for combating the enemy within our gates, a vast addition would be made to the sum of human happiness and many human lives saved. We have no intention of following Dr. WEBER through the subjects so admirably and genially dealt with by him. The lectures deserve to be read and studied, as they will be, and will neither bear compression nor need analysis. The point, however, which the lecturer appeared most desirous to urge upon his professional hearers was the pressing need there is for improving the facilities for the care of the consumptive poor; for modern science has clearly shown that the only treatment, whether prophylactic or curative, that is of avail is not the medicinal, but the hygienic and climatic—a watchful supervision of the invalid and his surroundings during the whole of his life. This implies not only a liberal expenditure of money, but the intelligent co-operation of the patient himself, and hence it is that the well-to-do and the educated are in a far better position for reaping the advantage of such treatment than the poor.

The conditions under which the poor live are precisely those which favour the progress and spread of consumption. To cope successfully with the disease, everything depends upon a sufficient and good supply of food, good clothing, well-regulated exercise varied by adequate rest, an ample supply of pure air; and who can say that a single one of these conditions is at the disposal of the vast majority of the phthisical? Nor when admitted into a hospital, not specially devised for the treatment of phthisis, is any advantage gained; for there is not a hospital physician who can deny the assertion of Dr. WEBER as to the unsuitability of the ordinary hospital life for the subject of phthisis. What then is required, and how is it possible to meet the demand? The magnitude of the undertaking involved in the answer to this question is such that a feeling of despair at its fulfilment is engendered. For it means the multiplication by hundreds of sanatoria such as the few now existing, and the placing them under qualified medical control. Dr. WEBER clearly showed that the requisites for such institutions are numerous if they are to be really efficient; but the guiding principle of them should be to afford an ample supply of pure air, sunshine, and protection from wet and wind. Dr. HASSALL'S admirable hospital at Ventnor may be taken as the type of what is needed in many parts of the country, if the amount of relief afforded is to be anything like commensurate with the extent of the disease.

If the striking and forcible manner in which attention has been drawn to this matter by Dr. WEBER shall issue, as we trust it may, in a great impetus being given to provision for the phthisical, and the bestowal of the advantages of pure air on those who are unable to seek it for themselves in mountain valleys, much will be gained. But how much will yet remain undone. The conditions of civilised urban life forbid the hope that phthisis can ever be banished from our midst. It is a melancholy reflection that, do what we

may, our efforts will only ameliorate, they cannot expel, this ever-present disease. Moreover, the number of the sick is so vast that, with the most extensive system of sanatoria it would be impossible to treat more than a minority.

Turning from this view of the subject, which concerns the philanthropist, to the arguments whereby Dr. WEBER proved the benefit ensuing upon the open-air treatment of phthisis, it will be admitted that his plea for a mountain climate was very forcible, whilst his refutation of adverse statements as to the efficacy of such climate was complete. But here, as in all departments of practice, the good derived from the treatment will depend upon the suitability of the case submitted to it; and we fear that there is not always sufficient discrimination shown in the choice of a health resort. To use the cant phrase that every case must be judged "on its own merits" is to imply that the physician should have a thorough knowledge of his patient's constitution, of the type of his pulmonary disease, and of the climatic conditions most suitable for him individually. Certain broad rules have been formulated as to the contra-indications for the tonic and stimulating influence of the sunshine and pure still air of high altitudes; but we still need the knowledge, which experience may ultimately bring, of the precise indications which will determine a preference for the converse climatic conditions. It is not that Madeira is better than Davos for all cases indiscriminately; but it is that for some forms of the disease Madeira is preferable and for others Davos. *Cæteris paribus*, that climate is the most suitable which will permit the invalid to enjoy as much of the day as possible in the open air; and dryness, sunshine, with freedom from wind, are the conditions which best allow of this. Dr. WEBER raised a note of warning against the danger of a health-resort like Davos being deteriorated by becoming too popular. The best way to prevent such a result is to seek for other regions equally favourable which can be utilised for the same purpose. Moreover, those who are responsible for the sanitation of these places should use every effort to render them free from endemic disease.

Annotations.

"Ne quid nimis."

THE UNIVERSITY OF LONDON AND THE PROPOSED TEACHING UNIVERSITY.

THE present relation of these bodies is briefly as follows. On Feb. 24th the special committee appointed by the Convocation of the University of London on Jan. 6th was reappointed, with full powers to promote the carrying into effect by the University of the objects of the Association for promoting a Teaching University. A meeting of the committee was held at Burlington-gardens on the 25th inst., and the following resolution was passed *nem. con.*: "That a subcommittee, consisting of the chairman and four members, be appointed to confer with the Association for promoting a Teaching University for London, or any committee of that body, and thereafter to prepare a draft scheme, or the heads or outline of a scheme, for the carrying into effect by the University of the objects of the said Association." The subcommittee will be composed of Lord Justice Fry, and Messrs. Savory, Anstie, Thiselton Dyer, and McDowall, as representatives of Medicine, Laws, Science and Arts respectively. The members of the Committee of Convocation have evidently now determined to take the first practical step towards the reform of the University, and, although there may exist doubts as to the possibility of their success in proposing a workable scheme that will be generally acceptable, they have our best wishes in their endeavours, for we feel assured that they are working in the right direction, and in the best possible manner to attain their ends.

THE NEW POISONS BILL.

THE new Poisons Bill which was introduced into the House of Lords by the President of the Council, and read for the second time last week, presents nothing of any positive interest to the medical profession. The omission to deal with the question of the Patent Medicines Stamp Tax is a subject for regret. Lord Carlingford, in his speech, showed that he was fully alive to the necessity for legislation on the subject, for he practically admitted that there was nothing to be said in favour of the retention of the stamp, except that it brought in an annual income of a few thousands. The Bill seems to have been very carelessly drafted, and the omission to include phosphorus and its preparations in the schedule of poisons is likely to provoke much adverse criticism. That the sale of colchicum should be in no way restricted is somewhat surprising, especially when it is remembered how frequently this drug is used for criminal purposes. Only as recently as last week we drew attention to the subject. We notice that in the first part of the schedule "all poisonous vegetable alkaloids" are included except morphia, which for some reason is retained in the second part. The insertion of the restrictive adjective "vegetable" in this phase is certainly a mistake, for there are many alkaloids and alkaloidal bodies of animal origin, some at least of which will probably come into use as therapeutic agents. Digitalin is expressly mentioned by name, obviously because, being a glucoside and not an alkaloid, it would not be included in the previous clause. The omission to insert the words "and all poisonous glucosides" is certainly strange, and indicates a marvellous ignorance of the technical points under consideration. We are pleased to find that special mention is made of lobelia and its preparations, and we trust that this will suffice to put a stop to the traffic which has long been carried on by herbalists and others. The nomenclature and orthography adopted by the framers of the Bill seem to us to be somewhat peculiar. Why the term "morphine" should be preferred to that of "morphia" and "emetic tartar" to "tartar emetic" we do not know. The Earl of Milltown has given notice that on the motion to go into committee he will move that it be referred to a select committee for consideration. This is certainly very necessary, and we trust the opportunity will be taken to move an amendment dealing with the repeal of the Patent Medicines Stamp Tax.

AREA CELSI.

THAT alopecia areata depends upon the growth of a fungus is a doctrine that has been often advanced only to be refuted, and has now few, if any, supporters. Nor can there be any doubt that mistakes have been made in the various attempts to settle what might seem to be a simple question, and certainly amongst those who have upheld the parasitic nature of the affection there has been little agreement as to the precise nature of the fungus concerned. It has been reserved for these days of microphytic pathology to revive the doctrine in a more refined form. Alopecia areata is due to the growth of a micrococcus, at least, so says Dr. von Schlen of Munich in a paper contributed to the current number of Virchow's *Archiv*. He

describes five cases, in all of which the stunted and diseased hairs were mostly the seat of colonies of micrococci, averaging 0·5 μ in diameter, some smaller ones being of the diplococcus form, and larger ones with median constriction. From their situation in the shaft, it would seem that they occurred in connexion with the ducts of the sebaceous glands, and it is inferred that they invade the hairs by these ducts. The micro-organisms were not found in any but the diseased hairs, and not universally in them. By cultures in agar-agar peptone it was ascertained that the organisms were distinctive in their mode of growth, and experiments were made with a view to ascertain whether they were really capable of transmitting the disease; on the human subject the attempt failed, but on white rats there appeared, on the spots where the material of some of the cultures had been rubbed in, scaly patches, over which the hairs at first became yellow-coloured, and then fell out. The writer reconciles the notion that these micro-organisms have a causal relation to the affection, with the other well-proved facts of its association with trophic disturbances—(e.g., vaso-motor derangements), by assuming that the occurrence of such disturbance prepares the soil for the growth of the micrococcus. Holding such views, he advocates, and has had good results from, epilation and the use of corrosive sublimate; and also urges the importance of cleanliness in the use of brushes, &c., as a prophylactic measure.

ARMY COMMISSARIAT AND TRANSPORT SERVICES.

THE subject of the defective organisation of the Commissariat and Transport services of the Army was incidentally brought under the notice of the House of Commons last week in the form of a motion by Colonel Stanley to reappoint the select committee nominated last year on the motion of Dr. Cameron. The committee had, before the close of the session, collected a great mass of information bearing on the subject, but had been unable to complete the inquiry and report their opinions. They had, however, laid on the table a voluminous Blue-book containing the evidence taken, and had unanimously recommended that they should be reappointed with a view to the completion of the report; and Colonel Stanley, in his official capacity of chairman of the committee, brought forward a motion to that effect. This was opposed by Lord Hartington on the ground that the heads of the Departments of Supply and Transport were at present so overtaxed by the work in connexion with the Nile and Suakim expeditions and the operations in Bechuanaland that it was quite impossible they could spare the time or give the attention necessary for the efficient working of such an inquiry, and that some of the officers whom it was considered of great importance to examine were now absent on service, To this he added, "that the evidence of the principal officers already examined before the committee showed that there had been no breakdown of any sort in the organisation, and that such difficulties as occurred arose from military exigencies of an exceptional character." From this opinion Dr. Cameron, who was one of the members of the committee, dissented, believing that there had been a very great breakdown, and he commented on the unprecedented course followed by the Government in opposing the reappointment of a committee which had unanimously recommended its reappointment. "He believed that a desire to burke further inquiry had a good deal to do with the refusal of the Government." Those who have read Dr. Cameron's "Romance of War; or, How the Cash goes in Campaigning" will, we believe, agree with him in thinking that the present organisation is very far from providing efficient service, and that to the system, and not to the officers who have to carry it out, must attach the blame of the shameful mismanagement and blundering which occurred in Egypt. Dr. Cameron was supported in his views by Colonel Milne Home and Sir H. Fletcher. Mr. Carington and Dr. Farquharson, while of opinion that the subject required full investigation, suggested that the appointment of the committee should be delayed till after Easter, "when the pressure of work connected with the troops in the Soudan going into summer quarters would be over." The motion for its reappointment was negatived by a majority of nineteen, but Dr. Cameron gave notice of his intention to move a resolution on the subject on going into supply on the army estimates. Dr. Cameron deserves great credit for the pertinacity with which he has kept the subject under notice, and for the clear and able manner in which he has shown up the results of the defective organisation. We have every confidence that he will find an opportunity to have the subject fully discussed, and that he will force upon the authorities the necessity for important alterations in the working of both the supply and the transport departments.

OVERWORK IN TELEGRAPH OFFICES.

OF the various public services the railway and the telegraph departments are two in which employés have probably to do harder and more continuous work than in any other. While each of them is contrived to meet the demands of sudden emergency, and to make use of all available time by day or night, it cannot be said that the working staff of either receives that consideration which is fairly due to it. The effects of this neglect have at times been painfully apparent in accidents and narrow escapes recorded on the line, and these we may hope have taught some lessons in organisation which were much needed, and are even now still better known in theory than observed in practice. The case of telegraph clerks is different. The risks arising out of overpressure do not usually concern the employers so much as the employed. They are such as tell severely on the health of individuals, many of them mere boys and girls, through the nervous and muscular strain of concentrated effort during a daily period of twelve hours. We do not forget that youth is, with many, a time of great constitutional elasticity. At that age a shock or a crisis may come and go and leave no lasting mark, and likewise high degrees of labour tension may be undergone and rallied from. At the same time one is forced to admit that much of the working material which passes into the telegraphic and every other service by competitive examination is by origin and habit physically unfit to sustain such effort. A shorter working time or greater division of duties appears therefore to be indicated, if we are to shield from needless hurt those whom we select on the present system.

"SIGNS OF DEATH."

OUR contemporary the *Echo* published a note on the 21st inst. headed "Life in the Coffin," and mentioned one of the supposed signs of death—flaccidity of the eyeball—as a test which, if trustworthy, should be universally known, but left the reader in ignorance of the degree of trustworthiness. It is well known that the state of tension of the eye varies according to the mode of death, being greatest in cases of asphyxia, especially where this has been produced by compression of the cervical veins, as in hanging. After death in all instances the eye sooner or later loses its natural lustre and prominence, but when this has so far developed as to be conclusive other signs of death are present. Without going through all the criteria—and their name is legion—that have been proposed to aid in the solution of the question, we may state that the advent of cadaveric rigidity and the supervention of decomposition are of infinitely greater value than the strongest evidence obtainable from an examination of the eye. They are, in fact, singly and collectively, the grounds which no reasonable person would contest.

RETARDATION OF THE PULSE IN MITRAL INSUFFICIENCY.

THE outcome of a scientific interpretation of the signs yielded by mere auscultation of the heart alone appears to be that such signs are inadequate of themselves to establish the nature of the lesion on which the murmur depends. In making this statement, we would have it understood that we wish to regard the matter solely on its scientific basis. Dr. Keyt of Cincinnati has done much in the cause of scientific diagnosis of cardiac disease by his papers on the Retardation of the Pulse in Valvular Disease of the Aortic and Mitral Orifices. He has found that abnormal retardation of the arterial pulse, and notably that of the carotid artery, is a real phenomenon of mitral insufficiency. It is present in all cases of pure organic mitral insufficiency, and is absent only in insignificant regurgitation or in regurgitation complicated by aortic insufficiency. The degree of retardation of the pulse is a measure of the amount of the regurgitation. The retardation may be present in two other organic conditions, and possibly in a third. In conjunction with an apex systolic murmur its presence is conclusive of mitral insufficiency. Compared with the apex systolic murmur, this sign is more positive, and distinguishes between harmful regurgitation and harmless conditions, which the latter does not. By the aid of the retardation of the pulse alone, a positive diagnosis may be made at once in any stage of the case under investigation, without waiting for the development of the usual sequelæ. Such are the conclusions at which Dr. Keyt has arrived. His evidence has been fully set forth in the *Journal of the American Medical Association* of Dec. 20th, 1884. The chief kinds of evidence adduced are the simultaneous tracings taken from the heart and the carotid artery of cases of pure mitral regurgitation, afterwards verified as such by post-mortem examination. For example, the normal interval between the time of the occurrence of the cardiac impulse and the pulse in the carotid, when the heart is beating 100 per minute, would be about one-seventeenth of a second. In the case of a boy aged nine having the signs of pure mitral regurgitation with a pulse rate of 100 per minute, the interval was found to be two-seventeenths of a second. The autopsy proved that the mitral regurgitant lesion was alone present. Dr. Keyt believes that he has also proved the point on an artificial schema of the circulation. The investigation is one which would well repay further attention.

THE ANTI-VACCINATION DEMONSTRATION IN LEICESTER.

AFTER the excitement of a crowd is over the sensible working men of Leicester will begin to ask themselves whether they have been making a very creditable appearance before the civilised world. Most of their own fellow-countrymen think they have been doing the reverse, and on the Continent and in the United States the opinion will not be very different. It is not necessary to maintain that vaccination is an absolute protective against small-pox, though few things are more clear than that it is so, if rightly used and at least once repeated. Nor is it necessary to deny that in very exceptional cases it has been followed by inconvenient effects, though these are so rare that many practitioners of standing have never seen them. To abandon a great good for the fear of incurring an infinitesimal evil is foolish indeed, and is to play into the hands of the medical profession, who have much more to gain from epidemics of small-pox, from which they absolutely protect themselves and their families, than they have from the slight and cheap operation of vaccination, performed for the most part by a few public vaccinators. It is only necessary to show that the fanatics of Leicester are placing themselves in opposition to the common sense of mankind, and of two evils prefer the infinitely greater one. It is well pointed out in *The Times* that in Leicester alone over 300 deaths from small-pox have been known to occur in one year. It cannot be doubted that, notwithstanding the comparative immunity of late years, the materials of future trouble are accumulating in spite of arrangements which are just as much violations of personal liberty as compulsory vaccination is. If Leicester could keep all its small-pox to itself, there would be some show of reason in its demand for exceptional legislation; but it cannot do so; and it is a poor prospect for the future if civil and religious liberty is to include the liberty to have small-pox and to spread it in all directions throughout the country, leaving its victims and their dependants to the mercy of the State. We commend these reflections to Professor Stewart and other members of Parliament who have found themselves able to make political capital out of the disparagement of laws which have saved life on a prodigious scale.

THE BICYCLE ACCIDENT AT CAMBRIDGE.

ON March 18th Mr. H. Gotobed, the borough coroner, held an inquest in the Master's Court, Trinity College, Cambridge, touching the death of Sir J. G. Aylmer, an undergraduate. From the evidence it appears that the deceased baronet had a severe fall from his bicycle, which stunned him for a time, and that he seemed to have recovered from the effects of the injury—so much so, in fact, that Mr. T. Hyde Hills, who attended him professionally, did not anticipate the fatal result. On the following evening he fell into a comatose state, from which he never rallied. It was known that deceased had been the subject of diabetes for some years. The symptoms of the fatal illness were those of diabetic coma, from so-called "Kussmaul's acetonæmia"; and the doctor certified the cause of death accordingly. Meanwhile the accident and its supposed result had been reported in the papers; and the coroner, on the information laid before him, decided—very properly, as we think—to hold an inquest. During the inquiry it transpired that the investigation before the court would not have been deemed necessary if Mr. Hills had stated in his certificate that the death was in no way attributable to the accident, or if he had given that assurance in writing at the request of the coroner. The misunderstanding led to a passage of arms between the coroner and Mr. Hills, which was described in the local papers as "a scene." The facts of the case were very obvious; and it only required a little tact to avoid the conflict of opinion that took place in open court. It is beyond doubt that the deceased had suffered from diabetes. It seems probable that his death was due to diabetic coma. Notwithstanding, we maintain that, in the interest of the public and the profession, it was not only desirable that an inquest should be held, but that a post-mortem examination should be made. Claude Bernard showed that puncture of the floor of the fourth ventricle of the brain in a rabbit caused temporary diabetes, and cases are on record in which a like result has followed injury to the head in the human subject. We know of one instance where the glycosuria was permanent. It seems not unreasonable, then, that the injury may have had some influence in producing the acute symptoms, or rather in determining the onset of the acetonæmic state. A valuable opportunity for pathological observation has unfortunately been lost. There is another reason why a post-mortem examination should have been made and the question of the bearing of the fall from the bicycle on the cause of death stated with precision. The deceased might have insured his life, and clearly a very important issue would then have to be determined—viz., whether the death was in way owing to the injury. The

jury found that "the fatal symptoms of the disease developed rapidly in consequence of deceased having been thrown from his bicycle"; upon which the coroner remarked "in the contemplation of the law, on that verdict the cause of death was the accident." It seems to us that the finding of the jury, although not improbably correct, was scarcely warranted by the medical evidence, for Mr. Hills discreetly declined to commit himself to the expression of a definite opinion as to the relation of the coma to the accident.

FURTHER EXPERIMENTS WITH CHOLERA VACCINIA.

THE experiments we noticed in a recent issue have been continued by Dr. Ferrán of Barcelona. Drs. Serañana and Jacques, in whom cholera vaccinia had been induced, were, nine days afterwards, again given injections of attenuated fluid, but this time entirely without effect. Several other experimenters submitted to similar treatment with the same fluid, with the result that they all suffered from headache, nausea, pyrexia, and general malaise, some of them being so severely affected as to be obliged to give up practice and keep their rooms. One of those whose symptoms were most severe was Dr. Llorens Gallart, who gives the following report:—"Having been inoculated by Dr. Ferrán, by means of a Pravaz syringe, with half a cubic centimetre of attenuated cholera fluid injected into each arm, three hours afterwards I began to feel severe pain in both arms, which increased until numbness supervened. There was also increasing general lassitude, a feeling of intense cold, which caused shivering for three hours; the pulse was 96, and there were nausea and intense frontal headache. All these symptoms reached their maximum twelve hours after the inoculation, causing dizziness. I was then obliged to lie down and cover myself up. The reaction, for which I had not long to wait, was intense. The pulse was 125 and full, the temperature 39° C. (102·2° F.), and there were great thirst, restlessness, and a condition bordering upon delirium. These symptoms lasted from the twelfth to the seventeenth hour after inoculation. After this had left me I still suffered from pain in the arms and from prostration, which, however, gradually passed off, ceasing completely in five days." Dr. Ferrán has also experimented on rabbits. Having protected some by a prophylactic dose—that is, having given them cholera vaccinia—he has proved that such are quite unaffected by double the dose which was found to be fatal to unprotected individuals. Further experiments are proposed to be made with cholera fluid, and also with that of other diseases.

NULLITY OF MARRIAGE.

ON March 19th Sir J. Hannen had before him another petition for a decree of nullity of marriage. It was sought to satisfy the court that the respondent, Mrs. Cannon, was insane at the time the marriage contract was entered into. The same line of argument was adopted as in the recent Durham case. It was proved by the medical evidence that five days after the wedding Mrs. Cannon was insane, and, further, that her father had been put under restraint for mental alienation. The judge decided the action on its general merits, holding that it was not proved that the respondent had shown unmistakable signs of insanity before the wedding ceremony; at the same time, he expressed his sympathy with the husband, who appears to have acted quite blamelessly. Dr. Savage is reported to have said that in his opinion the respondent "was insane before the marriage," and that, although "she understood to a certain extent what was taking place, she did not properly understand the matter." The terms of these statements not improbably represent the actual state of affairs, but yet it appears to us the doubt is too great to warrant the issuing of a decree. Apart from the legal construction of the evidence, it must not be forgotten that the possibility of the respondent's recovery is a very weighty factor against the advisability of releasing the petitioner from his contract. There should be unimpeachable testimony to warrant a decision that would leave a woman neither wife nor widow, yet something more than spinster. The history of this unhappy case gives additional proof of the correctness of the theory that hereditary neurotic taint strongly predisposes to unsoundness of mind.

THE MILITARY CLUBS.

WE have heard with much regret that there has of late been an apparently organised system of excluding from some of the service clubs certain classes of officers, and especially those of the Medical Department. We are very unwilling to believe that any body of gentlemen would be guilty of blackballing candidates who are eligible according to the rules of the club, and against whom there is nothing objectionable either socially or professionally. But our information has been derived from a quarter which leaves no doubt on our mind as to its accuracy, and unfortunately it is not the first time such a course has been followed in more than one of these clubs. We trust that the committees of the clubs where this has occurred may at once take steps to put down a practice which cannot fail to bring discredit upon the clubs themselves. We refrain from comment on the conduct of a few men—we feel sure they are but a few—who forget what is due not only to those whom they exclude, and who as a rule are quite as honourable as they are, but to themselves as gentlemen. We feel sure that no man of honour would feel himself justified in putting a black ball into the box of a candidate against whom nothing unfavourable can be alleged, and who is eligible by the rules of the club. On former occasions, when a similar practice was begun, the committees of the clubs succeeded in immediately checking it, and we cannot believe that on the present occasion their successors will fail either in the will or in the ability to bring about a similar result.

NERVOUS PYREXIA.

THE remarks on this subject in our issue of the 28th ult. having elicited some correspondence, we may take the opportunity of returning to the question. It is convenient to speak of heat centres without implying anything more than the mere existence of nervous apparatus capable of augmenting or diminishing the amount of heat formed in the organism. In discussing the subject we may leave aside the question of the localisation of the thermic centre or centres, merely stating that it is probable that the generation of heat in the organism is under the supervision of a principal centre and subsidiary centres, very much as is believed to be the case with the vaso-motor apparatus. The assumption that some such regulatory centres do exist is rendered most probable by all that is known of the physiology of temperature, and by nothing more so than the fact that a normal diurnal variation of temperature exists, and even manages to make itself apparent, when "fever" is present. Many modern authorities have advocated the view that some varieties of pyrexia are dependent on the direct action of the nervous centres regulating the temperature. In one of his Brown lectures, Mr. Victor Horsley strongly supports the doctrine that some cases of surgical interference give rise to pyrexia as the result of abnormal influences acting directly on sensory nerves, the influence of septic agents being supposed to be excluded. An excellent article on

the theory of a heat centre from a clinical point of view has been contributed by Dr. Hale White to the Guy's Hospital Reports, and Mr. Bowlby has written on the subject in the last volume of the St. Bartholomew's Hospital Reports. About a year ago Mr. Tait read a paper at the Obstetrical Society which tended to show that some of the rises in temperature observed in the puerperal state were the result of intrinsic disturbance of the heat regulating centres, and not due to the presence of poisons circulating in the blood. The subject is a wide one, and cannot here be fully discussed. But, granting the power of abnormal conditions of peripheral nerves to alter the production of heat in the organism, we do not see any reason why central disturbance of the same centres should not take place. Every argument of an *a priori* kind points to the conclusion that these things are possible. The difficulty is to prove the point. In any given case it would have to be shown that the nervous disturbance was primary if we would place on a safe foundation the occurrence of hysterical pyrexia. Now, it is possible that nervous disturbances of the kind under consideration may originate as the result of a poisonous state of the blood due to an idiopathic disorder of the processes of assimilation going on anywhere in the body, and it would be almost impossible to exclude the influence of such toxæmic conditions. Take, for example, those cases of pyrexia which have been supposed to be the direct result of emotional disturbance. Here it is perfectly legitimate to assume that the emotional element first deranges assimilation, which in turn causes the alteration of temperature either by the production of some abnormal material or in some other way. Even when sepsis is assigned as the cause of pyrexia, it is most probable that the septic poison acts on certain parts of the nervous system, and not directly by universal excitation of all the active tissues of the body. The considerations advanced, and many others that might be urged, place beyond cavil the conclusion that a definite proof of the existence of pure nervous pyrexia, however likely, is hardly susceptible of actual demonstration.

THE DENTAL REGISTER.

THE Dental Register for 1885 is issued. It shows that of dentists registered either on account of British qualifications, or as having been in practice as dentists before the Act came into force, there are 5255, or 36 less than in 1884. Those practising on foreign diplomas were 9, as against 5—viz., 6 Doctors of Dental Medicine of Harvard, 6 Doctors of Dental Surgery of Michigan. The explanation of the smaller number registered is probably to be found in the erasure of names by the registrar under clause 12. A case was heard in the Wandsworth Court a few days ago, in which a summons had been issued against Mr. A. G. Yeates for using the title of Surgeon-Dentist without being registered. But he was able to show that he had been registered up to 1880, and that his name dropped out merely by change of residence. Mr. Paget dismissed the summons, and ordered the complainant to pay costs.

SMALL-POX REGULATIONS IN ONTARIO.

A SPECIAL report has been issued by Dr. Bryce, Secretary to the Provincial Board of Health and Chief Medical Officer at Ontario, on an outbreak of small-pox in the township of Hungerford in Hastings County. The outbreak appears to have had its origin in infection brought from the Liverpool Industrial School. The first patient was an immigrant boy from that school who had left Liverpool on August 25th, had landed in Quebec with about forty other boys from the same class of school on Sept. 7th, and who sickened on Sept. 18th or 19th. The dates forbid the notion that the disease was contracted in Canada, and since there was no illness during the voyage, the infection was probably contained in the clothing or effects with which each boy was provided, and to which he had access during the course of his journey. This view is supported by the statement of the immigrant lad, to the effect that there was small-pox at the Industrial School two months before he came out. Certain steps are reported to have been taken with a view of preventing the spread of disease, which were doubtless very useful, but which certainly go beyond anything that is regarded as necessary in this country, where, as regards small-pox, the duty of self-protection by vaccination is deemed to suffice, in the place of many restrictions which it might otherwise be considered desirable to impose on others. Thus, lest any persons who had been exposed to infection should be making their way to other localities, instructions were conveyed to the station agent of the Ontario and Quebec Railroad to issue no tickets to persons other than those having passes from the medical officer of health. And again, with a view of preventing people from the northern part of the affected township from going south or east, police were placed on the roads leading into the districts referred to. We fear that if we adopted measures of this description in England, a new society would soon be formed to protest against the infringement of the liberty of the subject. But in the Far West such protests do not carry much weight in the face of a common danger to public health.

RELIEF IN PHYSICAL AND MENTAL SUFFERING.

IT is the frequent and painful duty of every member of the profession in active practice to detect in some of his patients, when consulted, it may be, about some trifling indisposition, the beginning of one of the many fatal diseases for which our art can suggest no remedy, but simple palliation. After such a diagnosis a medical man would lack common humanity who did not experience a feeling of commiseration for a fellow-creature thus afflicted. Few men can leave a patient thus doomed to a premature end without reflecting on the many shortcomings of the professional art it is his province in life to administer. To whom is it best that the painful intelligence should be made known? Should it be to the patient himself, young, full of hope and promise it may be, or to his friends? The embarrassment of such a position is at once apparent, and often to the patient it begets mistrust of a medical man's judgment; and not unfrequently to make the painful fact known to the friends begets an equal mistrust. Even with such a prospect before him the duty of a medical man is a plain one. Candour, if not to the patient, to his friends is clearly a medical duty, yet very often it is evaded as being too trying to discharge. In another class of cases, where recovery is not so utterly hopeless, but where danger is imminent, it is less easy to define the scope of a medical practitioner's duty. He very naturally leans on the resources of his profession, which under his administration have often before rescued a patient from an almost inevitable abyss. Under such circumstances hopefulness becomes in itself a remedy, and not infrequently a very potent one. To communicate his anxiety about the case to the patient's friends is often tantamount to communicating it to the patient; for it is seldom that such anxiety in immediate friends can be sufficiently suppressed to escape the sufferer's notice. But very few men indeed fail to feel the sense of responsibity thus incurred of permitting a fellow-creature to pass from this life unwarned, it may be unprepared. The foregoing reflections naturally lead to the question, Is it within the province of a medical attendant to administer more than to the physical ailments of the body? To speak, it may be, a

word of warning or of spiritual comfort is to pass from the domain of the physician to that of the divine. An opportunity to do this is a frequent occurrence to every practitioner. Men differ much in their sense of duty in this respect. Each heart must be its own guide under such circumstances. While indiscreet intrusion into the province of the clergy is to be deprecated, the fact is not to be lost sight of that medical men are members of the great Christian community to whom are given more than usual opportunity, intended not to be wasted, but used. These thoughts have been suggested by some extracts from the writings of Charles Kingsley, compiled by his wife, and dedicated to his memory, entitled "Out of the Deep." To be the means of placing such comfort within reach of the afflicted as this little work affords can scarcely be beyond the sphere of medical duty.

THE DRINK BILL FOR 1884.

IT is very unsatisfactory to find that the drink bill for last year is bigger by £872,981 than that for the year before. More beer and less spirits have been drunk. The Chancellor of the Exchequer will, nevertheless, lose £260,000 of revenue in consequence of the fact that beer pays so much less a tax than spirit. Thus British spirits are taxed 10*s.* per gallon, foreign spirits 10*s.* 4*d.* per gallon, and wine from 1*s.* to 2*s.* per gallon, according to strength; beer is only taxed $2\frac{1}{2}d.$ per gallon. Of two evils, beer and spirits, beer is perhaps the lesser; but it is by no means a drink that can be taken in large quantities with impunity. "He that drinks beer thinks beer," was Dr. Johnson's way of expressing its dulling effects on the brain; and it serves other organs, equally useful and essential, in the same way, giving ample work for physicians, and spoiling the best work of surgeons.

TROPHIC DISORDERS.

THE existence of special trophic nerves has always been denied by Dr. Brown-Séquard, who believes that the occurrence of acute eschars which appear after fracture of the vertebral column and myelitis may be avoided by preserving the skin from the irritating effects of the normal effete discharges. He believes the trophic lesions which result are due to an irritative lesion caused by simple section of the nerve aggravated by external injury. The importance of the external injury is attested by the following experiment. If a guinea-pig be rendered epileptic by section of the sciatic nerve, the lesions which usually appear on the leg are not produced if hemisection of the spinal cord be performed on the same side of the body. This hemisection prevents the animal from carrying the injured extremity to its mouth, and thus does away with the injury casually inflicted on the limb by the teeth.

MEASLES IN SUNDERLAND.

IT appears from the Registrar-General's recent weekly returns that the annual death-rate in Sunderland was equal to 42·1, 48·3, and 44·1 per 1000 respectively in the first three weeks of March; and it may also be noted that the rate averaged 32·7 in the first eleven weeks of this year. The main cause of this excess has been an exceptionally fatal epidemic of measles, which has caused 244 deaths within the borough since the beginning of the year. In addition to these deaths from measles, 20 from scarlet fever, 9 from whooping-cough, 7 from "fever," 4 from diphtheria, and 4 from small-pox have also been registered during the same period. Indeed, the principal zymotic diseases have caused a death-rate equal to 11·1 per 1000 during the first eleven weeks of this year, which is more than five times the mean death-rate from the same diseases in the twenty-eight large English towns dealt with by the Registrar-General. This disastrous waste of life, mainly of child life, will not have been entirely without compensation if it lead to an exhaustive inquiry into the causes which have conduced to the present exceptional mortality from measles. For it is impossible to doubt that the proportional mortality among the cases of measles during the present epidemic in Sunderland has been very considerably above the average. The proportional mortality of 89 cases treated last year in the London Fever Hospital was only 3·4 per cent.; this proportion would signify no fewer than 7000 cases in Sunderland since Christmas! It is worthy of note, moreover, that nearly 200 deaths from this disease occurred in Sunderland in 1882.

THE LATE MEDICAL OFFICER OF HEALTH FOR ST. PANCRAS.

AT a meeting of the Mansion House Council on the Dwellings of the People, held at the Mansion House on March 17th, the following resolution was unanimously passed, and the Hon. Secretary was requested to communicate the same to the press:—

"This Council learns with great regret that Mr. Shirley Murphy has felt himself compelled to resign his position as medical officer of health of St. Pancras, in consequence of the difficulties which he has encountered at the hands of certain members of his vestry, which have rendered it impossible for him to efficiently and conscientiously continue to discharge his duties. The exceptional abilities of Mr. Murphy and his wide experience in sanitary matters render his resignation an incalculable loss to the parish. This occurrence serves also to emphasise in the strongest manner the necessity for an immediate change in the relations of medical officers of health to the local authorities. In the opinion of this Council, the change should take the direction pointed out in its report, that medical officers of health should hold their office at the will of the Local Government Board only."

We most heartily endorse the spirit of the above resolution. Mr. Murphy is far too good a medical officer of health to be lost to the public service, and we confidently hope and trust that the resignation of his late office, however unfortunate for St. Pancras, will lead to his obtaining a more congenial post, as well as to the early amendment of the law as affecting the efficiency and independence of officers of health.

THE SPANISH HYGIENIC SOCIETY.

THE Spanish Hygienic Society has commenced its annual session under the presidency of Señor Pidal, Minister of Patronage. It does not seem to have been as successful as it was at first hoped it would have been in stirring the Government and the public to set about the reformation of the numerous sanitary defects which seem to be especially abundant in Spain. Many of the influential personages whose names formerly appeared as its members have from one cause or another dropped off. It is at present mourning the loss by death of one of its most active and zealous workers, Señor Mendez Alvaro. The *Genio Medico-Quirurgico* complains that the Government, though ready to assist and subsidise most trivial projects, is unwilling to lend a helping hand to such an important matter as the sanitation of the country.

COCAINE AS A HÆMOSTATIC.

IN the *Philadelphia Medical Times* of Feb. 21st, Dr. W. F. Waugh records a case of purpura with repeated hæmorrhages from the lips and gums, in which the application of a 4 per cent. solution of hydrochlorate of cocaine proved eminently successful, after the failure of many other hæmostatics to arrest the bleeding.

THE PRESIDENCY OF THE ROYAL COLLEGE OF PHYSICIANS.

IN accordance with custom, the Fellows of the College of Physicians meet in Comitia on the day after Palm Sunday, to elect a President. Although the office is an annual one, it is customary to retain a President in office for at least five years, and even longer, as was the case with Sir Henry Halford, who was President for twenty-two years, and Dr. Paris, for thirteen years. There is therefore no reason, unless it be Sir William's own expressed desire, why the present distinguished occupant of the presidential chair should not be re-elected for another term.

MILITIA SURGEONS.

WE would call the attention of all militia surgeons to the notice of motion given by Sir E. Wilmot for this day (Friday) to refer their claims for compensation to a select committee, and urge the necessity for militia surgeons to bring what influence they possess to bear on members of Parliament on both sides of the House to support the motion. If they do so there is every prospect of success, as on the last occasion, in 1883, the motion was defeated by only a very small majority, which was composed largely of members of the Government. This is not a party question, and the request to refer the case to a select committee is so reasonable that we hope the Government will see their way to grant it. It is not likely that the motion can come on till after Easter on account of the Redistribution Bill; this gives more time for applying to members of Parliament.

CAUTERISATION OF THE HARD CHANCRE.

THE treatment of excising the hard chancre does not appear to have met with favour by surgeons generally. M. Hallopeau has attempted the destruction of the primary sore by means of the powerful bichloride of mercury. In a recent number of the *France Médicale* he narrates a case of hard chancre in a man aged forty, on whom he practised the treatment of cauterising the sore by placing a thick layer of powdered corrosive sublimate thereon five days after the sore was first noticed; the powder was removed at the end of half an hour, and the ulcer dressed with dried lint. Some pain was experienced. The scab came away on the eighth day, and cicatrisation was completed by the sixteenth day. Nevertheless, the symptoms of secondary syphilis appeared in due course.

DEWSBURY RESPONSIBLE FOR SMALL-POX IN LEEDS.

AN instructive letter to the *Yorkshire Daily Post*, signed "Pax," points out the burden and cost which have been occasioned to Leeds by the occurrence of small-pox in three children who were born in the Dewsbury Union, and who, according to the lax views on such matters prevalent there, had not been vaccinated. The danger, however, has not terminated with them; four other cases have occurred in the same locality, and it is feared that others will arise. This, says the writer, is one result of the folly shown by the Dewsbury Board of Guardians in not enforcing the vaccination law within their union.

CREMATION IN ENGLAND.

WE understand that at the crematory erected near Woking station by the Cremation Society of England the body of a lady was on the 25th inst. reduced to ashes, in the presence of the representatives of the deceased. The cremation lasted one hour only, and was pronounced most satisfactory. This is, we believe, the first instance of cremation being publicly performed in England.

UNIVERSITY COLLEGE, LONDON.

THE vacancy caused by the resignation of Professor John Marshall, of the Chair of Surgery in University College, has been filled up, we are pleased to announce, by the appointment of Professor Marcus Beck; the chair carries with it the post of full surgeon to the hospital. We feel sure that the appointment of Professor Beck will meet with the approval of all who are interested in the welfare of the College.

DR. STORRAR.

WE understand that, in consequence of his increasing age, Dr. Storrar intends to resign the chairmanship of Convocation of the University of London at the next meeting in May. Dr. Storrar has most ably discharged the duties of the office for the long period of twenty-one years. We presume that, in accordance with the custom of the University, his successor will be chosen from the Faculty of Arts or Laws. An influential requisition has been signed asking F. J. Wood, Esq., LL.D., to allow himself to be nominated. Sir Julian Goldsmid's name has also been mentioned as a probable candidate.

SANITARY CONDITION OF QUETTAH.

THE Calcutta Correspondent of the *Daily News* telegraphs that there will be three divisions of the new Quettah Force, numbering 24,000 men, drawn from the three Presidencies, and that there will be a reserve of 11,000. We find confirmation of this in Reuter's telegram of the same date to the press generally. Such being the warlike movements necessitated by the state of affairs on the Afghan frontier, we take this opportunity to recall attention to the unsatisfactory sanitary condition of Quettah, and the large amount of sickness and mortality from enteric fever resulting therefrom. It was not long since we had occasion to draw attention in THE LANCET to the mortality in a British regiment marching thence down the Bolan Pass. We trust that the matter may receive the prompt attention it demands.

"STRANGE ADVENTURES" OF A BULLET.

A CASE of pistol-wound of the thorax has recently been recorded by Schmidt in which the bullet penetrated one of the left pulmonary veins, and then passed along it into the cavity of the left auricle, merely leaving a small erosion on the posterior wall of the vein. From the auricle the bullet must have gained access to the left ventricle, and must then have been forced into the aorta, and so down to the femoral artery, where the projectile was found, apparently accidentally, at the autopsy. The reporter declares that no other explanation of the presence of the projectile in the femoral artery can be given.

AN INSANITARY LOCALITY IN NORWICH.

A MEMORIAL has been presented to the Norwich Corporation complaining of the insanitary condition of a particular locality in New Catton. It was stated that "the house-drainage, frequently blocked, was conveyed into cesspools, some of which were only covered by trap-doors. Some of the wells had been condemned, as the water was unfit to drink. The cesspools were provided with a pipe which conveyed the filth into the undrained road, where it remained till it evaporated." The Sanitary Committee was urged by the member presenting the memorial to move in this matter as speedily as possible. It was, he observed, much more important for the welfare of the city than the introduction of party feeling and the ticketing of individuals "blue and white," "orange and blue," &c. A

member stated that he had previously complained of the condition of this locality. Some of the houses had no water supply, because the wells could not be used, and the water-company had not laid on water for the neighbourhood. The fountain head of typhoid fever was just such a locality as this, and if sanitary precautions were neglected a severe retribution was sure to follow. It was stated that the medical officer had said that such a condition of things ought not to be allowed to exist. The matter was referred to the sanitary committee, who, we hope, will take immediate steps to compel the owners or those who are liable to put an end to such a disgraceful state of things.

"CHARLEY KINGSTON'S AUNT."

IT has lately been rumoured abroad that the interesting medical novel bearing the above title, and published as "by Pen Oliver, F.R.C.S.," is in reality the work of Sir Henry Thompson. This rumour we can confirm, since we have the means of knowing that Sir Henry, during his last autumn holiday, gave up his hitherto invariable habit of painting a picture (usually for the Royal Academy), and devoted his leisure time to writing a medical story—a self-imposed task which was accomplished during the limits of his holiday.

IN answer to a memorial, signed by upwards of fifty Liberal members of Parliament, urging the repeal of the Contagious Diseases Acts before the present Parliament is brought to a close, Mr. Gladstone has replied that he fully recognises the importance of the representation, but he cannot pledge himself on the subject beforehand, especially at a moment when the time of Parliament is forestalled under exceptional circumstances. He anticipates, however, that some statement will in all probability be made before the end of the session indicating the views and intentions of the Government regarding this matter.

THE death is announced of Dr. Morison Watson, F.R.S., Dean of the Medical School, Curator of the Medical Museum, and Professor of Anatomy at Owens College, which took place on Wednesday last at Manchester, in his fortieth year. On February 3rd, whilst addressing the students, he ruptured a bloodvessel in the head, and had been almost continuously unconscious since. He was the author of numerous articles in scientific journals, his most important work being a contribution to the Reports on the Scientific Results of the Voyage of the *Challenger*.

CONCERNING the vacancies in the staff of the East Suffolk Hospital, a question has arisen as to the eligibility of an honorary physician, who was formerly for several years house-surgeon of that institution, on account of the distance of his present residence, which is about eight miles. A good deal of feeling seems to have been excited about the appointments, and the meeting of the governors has been adjourned for a month. There are three candidates for the two vacancies.

SURGEON I. R. LANE, attached to No. 1 Field Hospital, who was severely wounded in the assault on the Arab position at Hasheen on the 20th inst., has, we regret to learn, since died. Surgeon Lane entered the service so recently as August last. On the 22nd inst. Surgeon M. Digan, R.N., was severely wounded.

THE official report of the Commissioners appointed to inquire into the educational arrangements, &c., of the Queen's College, Ireland, has just been issued as a Parliamentary Blue Book.

AN election of a correspondent of the section of Medicine and Surgery of the Paris Academy of Sciences took place recently. The candidates were Dr. Hannover of Copenhagen, Sir James Paget, Dr. Leudet of Rouen, Sir Joseph Lister, and Dr. Panum of Copenhagen. For Dr. Hannover, who was elected, forty-one votes were given, against five for Sir Joseph Lister and three for Dr. Panum.

THE firm of J. F. Richter, of Hamburg, are about to publish a work entitled "Ueber Elephantiastische Formen," which has been edited by Dr. Esmarch and Dr. Kulenkampff. A large amount of information on the obscure group of diseases collectively known as "elephantiasis" may confidently be anticipated in this forthcoming volume.

WE learn from our contemporary, the *Bombay Gazette*, that on the eve of the occasion of Dr. Blanc leaving Bombay early this month on furlough to Europe, and retirement from the service thereafter, a large concourse of native medical practitioners met at a tea-party in his honour.

THE University of Vermont has (says the *Canada Lancet*) announced its intention of granting degrees in Medicine to registered British medical practitioners who pass a satisfactory examination in medicine, surgery, and midwifery. The fee to be charged is $30.

WE have received from the Fine Art Society an engraving which they have recently published of Professor Huxley. The likeness is an excellent one, and all who desire to possess a characteristic portrait of Mr. Huxley will do well to inspect this production.

DR. THOMAS BARLOW, F.R.C.P. Lond., has been appointed full Physician to the Hospital for Diseases of Children, Great Ormond-street, in place of Dr. Gee, resigned.

THERMO-ELECTRIC PROSTATOTOMY.

ENLARGEMENT of the prostate is one of the affections of the genito-urinary apparatus which, even in these days of operative triumphs, has been least successfully attacked by the surgeon. A fair estimate of the preference given to palliative measures may be inferred from a passage in Erichsen's last edition.[1] "The sole treatment of enlarged prostate consists in the regular use of the catheter, in order to draw off retained urine; and when once this treatment has been commenced, it must be continued for the remainder of life, the patient being taught to use the instrument for himself." This is in substance the orthodox teaching of the older, as of the modern, cliniques; but Professor Bottini of Pavia counsels a much bolder practice, which substantially amounts to making a free passage for the urine by thermo-electric cauterisation of the prostate.[2] Here is a case in point.[3] Signor P. A——, aged sixty-eight, from Noghera, had been unable for some years to micturate unassisted, when, at the commencement of last June, he consulted Professor Bottini at Pavia. The urine was then highly ammoniacal, with muco-purulent deposit, only evacuated through the catheter. The prostate was enlarged. The state of the urine and the power of the bladder were greatly improved by cold vesical irrigation, with solutions of boracic acid and of sulpho-carbolate of zinc; general nutrition and strength revived; the urine became neutral and then acid, and was expelled with impetus

[1] The Science and Art of Surgery, vol. ii., p. 1062, 1884.
[2] L'Iscuria da Prostatici Ingrossamenti del Prof. E. Bottini in Collezione Italiana di Letture sulla Medicina, diretta dal Dott. Giulio Bizzozero, vol. ii., No. 2. Milano, 1883.
[3] Gazzetta degli Ospitali, Feb. 11th, 1885, No. 12.

through the catheter. On the 5th of July, while the patient was under chloroform, a small quantity of urine having been withdrawn, Professor Bottini introduced his thermo-electric cauteriser into the bladder, turned the cauterising blade (A, Fig. 1) against the swelling, and lighted the cautery by connecting it with the battery poles, while a current of iced water, through B and C, kept the staff cold. The generation of cauterising heat at the desired part of the instrument, which is kept cool throughout its length, is rendered possible by its method of construction as a double-channelled metallic catheter. Within the inner tube are the insulated electric wires, leading down to a platinum plate, and heating it when the circle is completed. At the same time a stream of cold water circulates in the space between the two tubes, and prevents the diffusion of heat to the surrounding parts. In the case under notice the burning and consuming of the prostate were continued

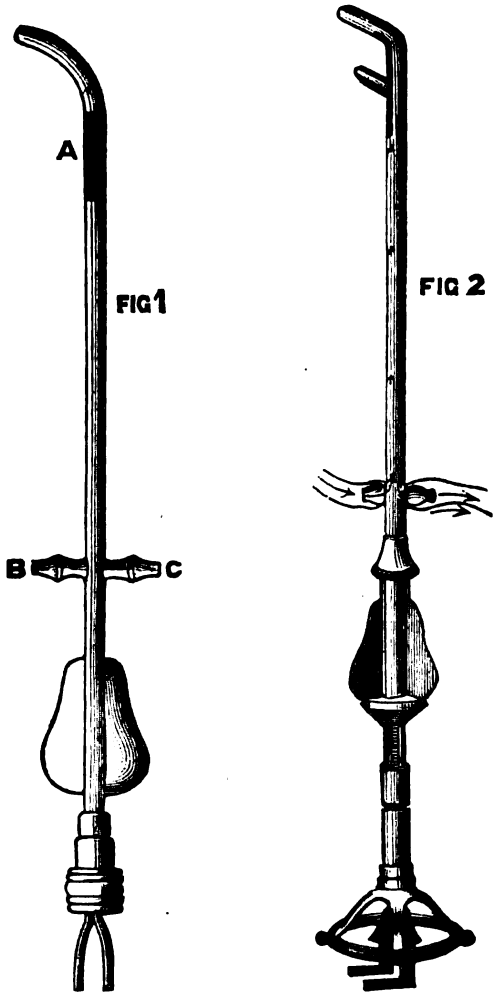

FIG 1

FIG 2

during forty-five seconds, when the instrument was withdrawn. On handing it to those present they found it cold throughout. A catheter was fixed in the bladder, and the urine drawn every three hours. No fever ensued, and belladonna suppositories proved effectual in relieving occasional vesical tenesmus. Four days later, the patient being in a very good state, the catheter was removed and the urine directed to be drawn every six hours, the bladder to be injected morning and evening with a 2 per cent. solution of sulpho-carbolate of zinc. On the 7th of August small sloughs were passed with the urine; they increased in quantity the following day, and gradually decreased without any trouble to the patient. The first natural emission of urine took place in drops twenty-four days after the operation; increasing day by day in quantity and impetus. The catheter continued to be used occasionally, from time to time, to prevent any possible accumulation. At the expiration of three months micturition was natural and the urine acid, clear, and healthy. At the date of the last report (January 23rd, 1885, six months and a half after the operation) the patient was fully restored to robust health. In reviving the tone of the bladder great assistance had been derived from the internal administration of the extract of nux vomica, and the local application of an induced electrical current.

Fig. 2 represents a thermo-electric incisor which Professor Bottini employs, according to the indications of particular cases, on the same principle as the instrument already referred to. He dwells on the advisability of accustoming the patient to the introduction of the instrument before the operation, which is performed in the ordinary lithotrity position. The rectum is to be previously evacuated with a bland enema; but unless the bladder be wholly, or nearly empty, injection of water is not necessary. The operation is not painful, and anæsthesia is only necessary in the case of timid or very sensitive patients. After the operation, tepid hip-baths are of great service, and so are belladonna suppositories.

To form an accurate judgment on the value of this procedure, it would be interesting to have records of a series of cases of prostatic enlargement treated by thermo-electricity. On one point especially, information is desirable—the permanency of the improvement. General experience teaches that eschars after burns contract much more than after incised wounds; and it remains to be proved whether the free passage made by the electric cautery in an enlarged prostate remains patent, or is liable to become the seat of thermo-traumatic stricture. Pending the answer, which only clinical experience can supply, the Professor of Pavia may be congratulated on having devised a method of treatment for enlarged prostate which has achieved some brilliant results, and promises to be a real addition to surgical therapeutics, in a malady which has hitherto baffled attempts at radical treatment.

UNIVERSITY OF DURHAM FACULTY OF MEDICINE.

THE following regulations for the examinations for the degree of Bachelor in Medicine of the University of Durham have been adopted, and will come into force on May 1st, 1885, viz.:—

There will be three examinations instead of two, as heretofore.

The subject of materia medica and pharmacy will be transferred from the final examination to the second examination, and the subjects of chemistry and botany from the second examination to the first examination.

The subjects of each examination will be as follows:—First examination: (1) elementary anatomy; (2) elementary physiology; (3) chemistry and chemical physics; (4) botany and medical botany. Second examination: (1) anatomy; (2) physiology; (3) materia medica and pharmacy. Third examination: (1) medicine; (2) surgery; (3) midwifery and diseases of women and children; (4) pathology; (5) medical jurisprudence; (6) therapeutics; (7) public health.

Candidates will be admitted to each of these examinations after duly certified attendance at a recognised medical school on courses of instruction in the various subjects of the examination, as set forth in the schedules of certificates issued by the University. Each examination must be passed in its entirety before the next can be proceeded with.

As heretofore, each candidate before presenting himself for the third or final examination must have spent one winter and one summer session in attendance at the University of Durham College of Medicine, Newcastle-on-Tyne, and must have passed one of the recognised arts examinations.

A candidate who has passed the first examination of the Conjoint Board in England of the Royal College of Physicians of London and the Royal College of Surgeons of England will be exempt from the first examination of the University of Durham, except in the subject of chemistry, on which he will be re-examined.

A candidate who has passed the first and second examinations of the University will be exempt from the first and second examinations of the Conjoint Board, and will be entitled to present himself for the final examination of the Board on the completion of the necessary curriculum.

Full particulars of the examinations, together with synopses of the subjects schedules of certificates, and any information

required, may be obtained on application to the Registrar of the University of Durham College of Medicine, Luke Armstrong, M.D., 26, Clayton-street West, Newcastle-upon-Tyne.

WILLS OF MEDICAL MEN.

THE will of Edward James Parry, M.D., late of Swan Hill, Shrewsbury, who died on Dec. 19th last, was proved on the 19th ult. by Mrs. Bertha Parry, the widow, and Mr. Malcolm Scarlett Parry, the son, the acting executors, the value of the personal estate amounting to over £15,000. The testator, subject to the payment of a few legacies thereout, leaves all his property upon trust for his wife for life; and at her death £3500 upon trust for his daughter Bertha Susannah Jones, certain railway stocks upon trust for his daughter Caroline Helen Parry, and the ultimate residue of his property to his said son.

The will of St. George Wade Tucker, M.D., retired Surgeon-Major, Her Majesty's Indian Army, formerly of the Island of Bermuda, but late of Edmondsham House, Bournemouth, who died on Jan. 13th last, was proved on the 6th ult. by Mrs. Julia Catherine Maréchaux, the sister, one of the executors, the value of the personal estate exceeding £6000. The testator leaves all his property upon trust for his said sister for life, and then for his two nieces, Georgiana Fanny Maréchaux and Alice Louisa Maréchaux.

The will of Charles Langstaff, M.D., late of Southampton, who died on Nov. 9th last at Havre, was proved on the 2nd inst. by Mrs. Anne Langstaff, the widow and sole executrix, the value of the personal estate exceeding £3600. The testator gives all his real and personal estate to his wife absolutely.

The will of John Toswill Veitch, M.D., of "Brahrang," Warrington-road, Ipswich, who died on Nov. 10th last at King's-road, Chelsea, was proved on the 24th ult. by Mrs. Celia Gertrude Veitch, the widow, Mr. Harry James Veitch, the nephew, and Mr. Thomas Drew Dewdney, the executors, the value of the personal estate exceeding £2000. The testator bequeaths all his articles of personal, domestic, or household use or ornament, excepting some specially bequeathed, to his wife; £250 to his nephew, Arthur James Veitch, of Brisbane; and numerous legacies to relatives and others. The residue of his real and personal estate, including his share in some plantations abroad, he leaves upon trust for his wife for life; and then, subject to an interest in part given to his brother Robert and his wife Sarah, for his nephews and nieces, Peter Christian, Masseyna, Quinten Reid, Walter, Robert Louis, Maria Rebecca, Helen Mary, Alice Susan, Florence, and Anna Veitch, in various proportions.

The will of Nathaniel John Haydon, M.D., F.R.C.S., late of Tiverton, Devon, who died on December 6th last, was proved on the 27th ult. by Mr. John Nathaniel Haydon, one of the executors, the value of the personal estate exceeding £1500. The testator leaves his property upon trust for his daughters, Mary and Edna Kate; but his son Edgar is to be allowed to select a medical book or instrument.

The will of James Robertson, M.D., formerly of Pall Mall, but late of 14, Queen's-square, Bath, Physician and Surgeon, who died on December 2nd last, was proved on the 8th ult. by Mr. William Woodham, the sole executor, the value of the personal estate exceeding £1300. The testator, after giving some legacies, gives all his real estate and the residue of the personalty to his brothers William and Robert.

The following legacies have recently been left to hospitals and other medical institutions:—Mr. William Hartridge, of the Stock Exchange, and of Addelam, Upper Deal, Kent, £200 to the Royal Hospital for Incurables, Putney.—Mr. Henry Skynner, late of Temple Chambers, 32, Fleet-street, Solicitor, and of 6, Neville-terrace, Onslow-gardens, South Kensington, £500 to St. Bartholomew's Hospital, in commemoration of his brother, and to be called the "Robert Charles Skynner Prize Fund," the income to be given annually to the student passing the best examination in the anatomy of the human body and the best treatment for scarlet fever and rheumatic fever; and 50 guineas each to the Seamen's Hospital Society, Greenwich, St. Bartholomew's Hospital, St. Mark's Hospital for Fistula, Charterhouse-square, St. Mary's Hospital, Paddington, the London Hospital, Whitechapel, the Cancer Hospital, Fulham-road, and the Hospital for Consumption, Fulham-road.—Miss Mary Clark, of 10, Albert-road, Regent's-park, £400 to the British Home for Incurables; £300 to the Central London Ophthalmic Hospital, Gray's-inn-road; £250 each to the Royal Free Hospital, Gray's-in-road, the University College Hospital, Upper Gower-street, and the City of London Hospital for Diseases of the Chest, Victoria-park; and £200 each to the Hospital for French Rufugees, Victoria-park, King's College Hospital, and the Royal Westminster Ophthalmic Hospital, King William-street.—The Right Hon. Mary Anne, Viscountess Torrington, £200 each to the Brompton Hospital for Consumption, and the St. Andrew's Convalescent Home, Folkestone.—Mr. Edward Jauverin Emanuel, of 15, Austin Friars, Solicitor, and of 4, Hyde-park Mansions, Hyde-park, £20 each, free of legacy duty, to University College Hospital, the London Hospital, St. Mary's Hospital, Paddington, the Male Lock Hospital, the Female Lock Hospital, Ormond-street Hospital for Sick Children, and Portsmouth Hospital, Landport.—Mr. Alfred Tylor, of 2, Newgate-street, and of Shepley House, Carshalton, £100 each to the Invalids' Home, Stamford-hill, and the North-Eastern Hospital for Children.—Mr. William Overend, Q.C., of Lincoln's-inn, and of West Retford House, Retford, Notts, £100 to the Sheffield General Infirmary.—Mr. George Trist, of 62, Old Broad-street, and Eliot Lodge, Sydenham-hill, £200 to the Sussex County Hospital, and £50 each to the Charlwood Dispensary and the Sydenham Home for Sick Children.—Mr. Henry William Franklyn, of Shedfield Lodge, Droxford, Hants, £50 each to the Bristol General Hospital, the Bristol Royal Infirmary, the Bristol Deaf and Dumb Institution, and the Bristol Home for Sick Children.—J. L. Kelly, £50 to the Hospital for Incurables, Dublin.—Miss Ross, £500 to the Adelaide Hospital, and J. Castles, £100 to the same institution.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Carlisle Urban District.—Carlisle has now an estimated population of 37,300. In calculating the death-rate fifty-three weeks are taken as included in the year, and with this the rate is 21 per 1000 living. The death-rate from the principal zymotic diseases was very low, only reaching 1 per 1000; indeed, it is the lowest of the twenty-eight towns in England which are comparable with Carlisle. A good deal of valuable information is tabulated as to the conditions which led to such diseases as enteric fever, and the authority have, in consequence, had it specially brought under their notice that it is absolutely necessary to maintain a proper control over houses whilst they are being built if the common causes of the disease are to be eradicated. No town like Carlisle should be without a skilled officer to see that really efficient bye-laws as to new buildings are being properly carried out. Merely to look at and to pass plans affords no sufficient guarantee as to the character of the actual work that will be executed. It is somewhat curious that eleven cases of enteric fever were found to be associated with the existence of nuisances, as from animal ordure at slaughter-houses; and Mr. Brown adverts in his report to the fact that, elsewhere, such a condition has been regarded as favourable to a *de novo* origin of the contagium. Under any circumstances the conditions ascertained speak but ill for the control and inspection of slaughter-houses in Carlisle; and Mr. Brown does not fail to point out to his authority the defects that call for remedy in this direction.

Rochester Urban Sanitary District.—Dr. Sladden Knight states the death-rate to have been 20·8 per 1000, which, by deducting deaths in hospitals, is reduced to 16·8. The death-rate under one year was 191 per 1000 births. The zymotic death-rate was 3·2, which is partly due to deaths in St. William's Hospital from infectious disease contracted outside the district; also to the excessive temperature in August and September, which caused many infantile deaths from diarrhœa. There was only one fatal case of small-pox which was contracted in London. Great care was taken both in this instance and in such others as occurred, by vaccination, fumigation, disinfection, &c., to prevent the spread of the disease with such success that in no instance

did any second case occur. The existence of St. William's Hospital as a means of isolation for infectious cases was of very great advantage. The patients have been much pleased with the attention they received in it, and the mortality has been very moderate. The governors have wisely desisted from demanding payment for maintenance from those in needy circumstances, rightly judging that as the public generally benefit by the removal from their midst of infectious cases, so the public ought not to grudge the expense of such protection.

Chesterfield Rural District.—In this extensive colliery district great improvement has been effected during recent years under the administration of Dr. Angus Mackintosh. The death-rate for 1884 was 17 per 1000. Scarlet fever periodically adds materially to the mortality. The district contains a large population of very independent workpeople at the child-bearing age, and hence there is a large number of children. In addition to this, and notwithstanding numerous efforts in this direction, it has not yet been found feasible to secure a combination of authorities for the purposes of hospital provision. The result is a recurring necessity for school-closing, which must seriously interfere with education, and which might otherwise not be requisite. During 1884 four elementary schools were thus closed. Measles again seriously affects the infantile population, but having regard to the fact that this disease is probably infective at a stage before it is at times even recognisable, the chances of staying its prevalence in such a district as this are not very hopeful. Some cases of enteric fever in connexion with contaminated water are recorded, and outbreaks of small-pox have occurred, which go to show the great need for adequate means of isolation. Amongst the several places still needing an improved water-supply, Dr. Mackintosh especially refers to the village of Gleadless Townend, where repeated attacks of enteric fever have occurred. Many other matters are adverted to in this interesting report, and as we look through the record it gives of excellent sanitary administration in a district which, mainly owing to Dr. Mackintosh's energetic labours, has been one of the foremost in carrying out structural sanitary works, we can only regret the fact that, now that the most burdensome part of the work is finished, a majority of the authority fail to appreciate as they should do the services which have brought about so many satisfactory results.

Halifax Combined District.—This important district comprises the Halifax rural and seventeen urban districts. Taking the district as a whole, the death-rate has been 18·8 per 1000, which is certainly too high; it has varied from 12·5 in Luddenden Foot to 25·5 in Rastrick. The zymotic death-rate for the entire district was 2·1 per 1000. Rastrick, where the highest rate of mortality prevailed, is a place for premature marriages and neglect of children, and many of the latter die, before reaching the age of five years, of scarlet fever and other zymotic affections. Dr. Britton shows by his record of work in connexion with each sanitary district that a careful supervision is maintained. Analyses of suspected waters are regularly made, and numerous works both of water-supply and drainage are carried out with a view of remedying the defects which come under notice.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN twenty-eight of the largest English towns 5823 births and 4018 deaths were registered during the week ending the 21st inst. The births exceeded by 9, and the deaths by 391, the average weekly numbers during 1884. The annual death-rate in these towns, which had been equal to 20·6 and 22·1 per 1000 in the preceding two weeks, further rose last week to 23·5. During the first eleven weeks of the current quarter the death-rate in these towns averaged 22·6 per 1000, against 24·4, the mean of the rates in the corresponding periods of the nine years 1876-84. The lowest death-rates in these towns last week were 14·0 in Derby, 17·4 in Birkenhead, 18·2 in Brighton, and 19·0 in Portsmouth. The rates in the other towns ranged upwards to 29·6 in Newcastle-upon-Tyne, 31·7 in Cardiff, 32·9 in Manchester, and 44·1 in Sunderland. The deaths referred to the principal zymotic diseases in the twenty-eight towns, which had ranged in the preceding ten weeks between 356 and 398, rose last week to 443. These included 164 from measles, 119 from whooping-cough, 41 from scarlet fever, 37 from "fever" (principally enteric), 32 from diphtheria, 26 from diarrhœa, and 24 from small-pox. No death from any of these zymotic diseases was recorded last week either in Brighton or in Blackburn; whereas they caused the highest death-rates in Bristol, Cardiff, and Sunderland. The highest death-rates from measles occurred in Bristol, Cardiff, and Sunderland; from whooping-cough in Plymouth, Norwich, and Bristol; from scarlet fever in Wolverhampton; and from "fever" in Norwich. The 32 deaths from diphtheria in the twenty-eight towns included 20 in London, 3 in Leeds, 2 in Liverpool, and 2 in Salford. Small-pox caused 43 deaths in London and its outer ring of suburban districts, and 1 each in Liverpool, Manchester, Bradford, Sunderland, and Newcastle-upon-Tyne. The number of small-pox patients in the metropolitan asylum hospitals situated in and around London, which had declined in the preceding four weeks from 1223 to 898, had further fallen to 830 on Saturday last; the admissions, however, which had been but 94 and 104 in the preceding two weeks, further rose last week to 137. The Highgate Small-pox Hospital contained 83 patients on Saturday last, 8 cases having been admitted during the week. The deaths referred to diseases of the respiratory organs in London, which had been 374 and 455 in the preceding two weeks, further rose last week to 487, and exceeded the corrected weekly average by 3. The causes of 101, or 2·5 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Leicester, Newcastle-upon-Tyne, and Derby. The largest proportions of uncertified deaths were registered in Oldham, Hull, and Halifax.

HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 22·8 and 24·4 per 1000 in the preceding two weeks, were 24·2 in the week ending the 21st inst., exceeding by 0·7 the mean rate during the same week in the twenty-eight large English towns. The rates in the Scotch towns last week ranged from 13·8 and 17·7 in Aberdeen and Dundee, to 29·0 in Paisley and 29·9 in Glasgow. The 590 deaths in the eight towns included 35 which were referred to whooping-cough, 28 to measles, 7 to scarlet fever, 6 to diarrhœa, 5 to diphtheria, 4 to "fever" (typhus, enteric, or simple), and not one to small-pox; in all, 85 deaths resulted from these principal zymotic diseases, against 71 and 88 in the preceding two weeks. These 85 deaths were equal to an annual rate of 3·5 per 1000, which was 0·9 above the mean rate from the same diseases in the twenty-eight English towns. The 35 deaths from whooping-cough showed a further increase of 13 upon the numbers returned in the previous two weeks; 17 occurred in Glasgow, 5 in Edinburgh, 4 in Greenock, and 4 in Leith. The 28 fatal cases of measles also showed a further increase upon recent weekly numbers, and were all returned in Glasgow. The deaths from scarlet fever, however, which had been 17, 12, and 13 in the previous three weeks, declined to 7 last week, of which 3 occurred in Glasgow and 2 in Edinburgh. Four of the 5 deaths from diphtheria and 2 of the 4 from "fever" were returned in Edinburgh. The 6 deaths attributed to diarrhœa were less than half the number in the corresponding week of last year. The deaths referred to acute diseases of the respiratory organs in the eight towns, which had been 119 and 122 in the previous two weeks, further rose to 124 last week, and exceeded by 26 the number returned in the corresponding week of last year. The causes of 94, or nearly 16 per cent., of the deaths registered in the eight Scotch towns last week were not certified.

HEALTH OF DUBLIN.

The rate of mortality in Dublin, which had been equal to 30·3, 32·7, and 39·5 per 1000 in the preceding three weeks, declined to 34·6 in the week ending the 21st inst. During the first eleven weeks of the current quarter the death-rate in the city averaged no less than 33·5 per 1000, the mean rate during the same period not exceeding 21·5 in London and 20·4 in Edinburgh. The 234 deaths in Dublin last week showed a decline of 33 from the high number returned in the previous week, and included 16 which were referred to measles, 6 to whooping-cough, 3 to "fever" (typhus, enteric, or simple), 3 to diarrhœa, 2 to scarlet fever, and not one either to small-pox or diphtheria. These 30 deaths corresponded

with the number in the previous week, and were equal to an annual rate of 4·4 per 1000; the rate from these diseases last week in London and Edinburgh did not exceed 2·3 and 2·7 respectively. The fatal cases of measles, which had been 8, 10, and 11 in the previous three weeks, further rose to 16 last week, and exceeded the number in any previous week of this year. The 6 deaths from whooping-cough also showed a further increase upon recent weekly numbers. The deaths referred to scarlet fever, "fever," and diarrhœa showed, however, a decline. Six deaths from violence, but only 3 inquest cases, were registered within the city; and 67, or more than a quarter, of the deaths were recorded in public institutions. The deaths of elderly persons showed a marked decline from the number in the previous week. The causes of 24, or more than 10 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

THE VOLUNTEER REVIEW.

IT will be interesting to follow the medical arrangements for the marching columns to Brighton on Good Friday, since the authorities at the Horse Guards and Whitehall-yard are anxious to complete them in the most perfect manner. It is proposed to carry them out in every detail as though the columns were acting during hostilities, an arrangement that never has as yet (except in one imperfect instance) been detailed in the regular army during the progress of any war. The present medical field service has of late been considerably improved, and this opportunity is taken to try its adaptability to the service. It is an honour to the Volunteer Medical Staff to be singled out as the pioneers in so important a matter, and we trust that the zeal of the Volunteer surgeons will afford every assistance to these endeavours of Government. One prominent feature in the day's details will be the first appearance of the bearer companies, whose services have just been accepted by Government, and which will be enrolled in time for the Review. These bearer companies, complete in every detail, will follow up the first aid given by the regimental surgeons and bearers to the wounded, who will be transferred in order to the rear, where they will pass into the hospital which accompanies the column. Of course to carry this out a number of men will be detailed as wounded, and these, with their tickets describing their wounds, will be attended at once by the regimental officers, who, passing on, will leave them in safety, to be taken up by the bearer companies. These bearer companies will number from 100 to 120 men, with the full complement of surgeons; and the hospital and brigades will be credited with their full staff. The details are being elaborated by Surgeon Cross, Grenadier Guards, who is well known in connexion with his late appointment at Aldershot as instructor to the Army Medical Staff; and under his efficient aid in the route as chief medical officer, we may expect to find success in the proposed scheme.

WAR OFFICE.—Army Medical Staff: The following Surgeons-Major to be Brigade Surgeons:—Austin Jonas Ferguson, vice William Skeen, M.D., promoted; John Robinson, vice Alfred Malpas Tippetts, promoted; St. John Killery, vice Rowland Wimburn Carter, granted retired pay; William Alexander Gardiner, vice Chamney Graves Irwin, M.B., promoted; George Scott Davie, M.D., vice William Cathcart Boyd, granted retired pay; Surgeon-Major Donald McEwen, M.B., retires from the service, receiving a gratuity; Surgeon Henry Brougham Guppy, M.B., has been placed on the retired list of his rank.

INDIA OFFICE.—The Queen has approved of the retirement from the service of the undermentioned officers of Her Majesty's India Military Forces:—Brigade Surgeon Robert William Cockerill, of the Madras Army. The undermentioned officers are granted a step of honorary rank on retirement:—Deputy Surgeon-General Colvin Smith, M.D., C.B., of the Madras Army, to be Surgeon-General; Brigade Surgeon Charles Kilkelly, of the Bengal Army, and Brigade Surgeon Robert William Cockerill, of the Madras Army, to be Deputy Surgeons-General; Surgeon-Major Thomas Gray Skardon, of the Bengal Army, and Surgeon-Major William Edward Allen, of the Bengal Army, to be Brigade Surgeons.

Surgeon-Major R. Boustead, Her Majesty's Indian Medical Staff, has been appointed Senior Surgeon 1st Divisional Field Hospital at the front with Her Majesty's Indian Forces in the Soudan.

Dr. A. Barry, of the 2nd Bombay Lancers, has been appointed to act as Surgeon to the Goculdas Tejpal Native General Hospital in Bombay, vice Dr. Vandyke Carter, on leave.

Surgeon-Major E. H. R. Langley, Indian Medical Service, Bombay, has been promoted to be Brigade Surgeon, vice Brigade Surgeon W. P. Partridge, retired.

Deputy Surgeon-General W. J. Moore, Indian Medical Service, Bombay, has been permitted by Her Majesty's Secretary of State for India to return to duty.

Brigade Surgeons John Jones and William Henry Kirton, Indian Medical Service, Bengal, have been permitted to retire from the service.

ADMIRALTY. — The following appointments have been made:—Fleet Surgeon William Graham, to the *Tamar;* Surgeon Arthur S. Nance, to the *Shannon;* Surgeon Henry J. Gordon, to the *Tamar;* Surgeon Alexander F. Harper, to the *Sea Lark;* Surgeon Edward B. Townsend, to the *Sea Flower;* Surgeon Edward W. von Thuzelmann, to the *Martin;* Surgeon George A. Dreaper, to the *Nautilus;* Surgeon William H. O. Meara, to the *Pilot;* Surgeon William W. Jacobs, to the *Liberty.*

MILITIA MEDICAL STAFF.—Surgeon-Major Richard Commander Kibbler, 7th Battalion, the Rifle Brigade (the Prince Consort's Own), resigns his commission, also is permitted to retain his rank, and to wear the prescribed uniform on his retirement; Surgeon William Sproule Love, 4th Battalion, the Royal Inniskillen Fusiliers, to be Surgeon-Major.

THE VOLUNTEER MEDICAL STAFF CORPS.—Acting Surgeon James Cantlie, M.A., M.B., from the 7th Middlesex (London Scottish) Rifle Volunteer Corps, to be Surgeon-Commandant; Surgeon John Lees Hall, A.M.D., to be Adjutant.

ARTILLERY VOLUNTEERS.—1st East Riding of Yorkshire: Surgeon Eleazar Sherwood, M.D., resigns his commission; also is permitted to retain his rank, and to continue to wear the uniform of the corps on his retirement.

RIFLE VOLUNTEERS.—2nd Lanarkshire: Surgeon William Crawford, M.D., resigns his commission.—1st Dumbartonshire: Lieutenant Robert Braid resigns his commission; Alexander Martin, Gent., M.B., to be Acting Surgeon.—2nd (South) Middlesex:—Stephen Henry Moore, Gent., to be Acting Surgeon.

Correspondence.

"Audi alteram partem."

THE UNIVERSITY OF LONDON.

To the Editor of THE LANCET.

SIR,—The long-felt discontent with the course pursued by the University of London has at length found expression, and the hitherto half-suppressed murmurs of dissatisfaction have now shaped themselves into active demands for change. It is far from my desire to interfere in so good a cause; nor do I propose to express an opinion as to whether the University has been the important factor in the improvement of general education as claimed by some of its supporters; or whether it is necessary or desirable that the general practitioner of medicine should possess a degree; or whether the present standard of the University should or should not be lowered, tempting as these and similar questions are to discuss. But I venture to ask for space to indicate a side of the question that, so far as I know, does not seem to have obtained the consideration it deserves, and neglect of which appears to me likely to lead to a waste of time and energy.

Beyond the very general feeling that something should be done to render the University of London more worthy of its name, there cannot be said to be very much agreement, and in the first steps of such an undertaking, when each one wishes to ride his own particular hobby, such diversity is not to be wondered at, and the remedies proposed are almost as varied as the grounds of complaint. After a good deal of preliminary skirmishing the attack upon the existing institution may be said to have taken two lines, and the schemes that are now in process of maturing, although widely

different from each other, have, as may be supposed, several points in common; and either would, if it succeeded, result in establishing a very different University from that we at present possess. The Association for Promoting a Teaching University for London, and the Council of the Metropolitan Counties Branch of the British Medical Association, alike desire to give a greater direct share in the control of the University to actual teachers engaged in instruction, and by associating the examination with teaching, would aim at rendering the degrees granted a better and truer evidence of education and real knowledge than the certificates of successful cramming, which they are very generally regarded as being at present.

The work that the Association for promoting a Teaching University for London has marked out for itself includes among other items the "entering into communication with the Senate and Convocation of the University of London, with the governing bodies of all other teaching institutions, with the authorities of the legal and medical professions, and other bodies." As this stupendous labour is assigned to a committee of thirteen gentlemen, most or all busily occupied by their professions, it is not reasonable to expect any result of their work for some time to come. To aid them in their communication with the University of London Convocation has appointed a committee of forty of its members, with power to confer with the Senate, in order to "promote the carrying into effect by the University of the object of the Association," which Convocation, at its meeting on the 24th ultimo, declared would "add to the importance and usefulness of the University."

The Council of the Metropolitan Counties Branch of the British Medical Association, dealing with a much smaller subject than the other body—viz., the wants only of medical students—have advanced considerably on the road, and having drawn up, discussed and accepted, a most exhaustive report, absolutely conclusive from its point of view, are now on their way to confer with the Senate in support of their objects, and, failing in obtaining the concession they desire, are prepared to take such steps as practically amount to establishing another degree-granting body—i.e., another university. No such alternative to the failure of their proposals is suggested by the committee of the other Association, who profess in their objects the utmost loyalty to existing institutions; although it would not seem very clear how far their respect for the present University would prevent the independent prosecution of their purpose should they fail in obtaining their object.

Now, are not these bodies, with their excellent aims, somewhat reckoning without their host? I would ask, Can the present University of London entertain the proposals of either of these suppliants? The neglect with which the tentative proposals in the direction of "conferring a substantive voice in the government of the University upon those engaged in the work of university teaching and examining" hitherto made by Convocation have been treated by the Senate, does not argue a very strong wish on their part to assent to any change, nor does it seem to me that the reverse could be expected, and it is more than probable that when the proposals reach that august body with the weight conferred by the distinguished individuals now approaching them they will be met by a simple *non possumus*. Reference to the charter of the University would seem to show that the course pursued by the Senate is quite in accordance with their constitution, and that it is not in their power to alter themselves in accordance with the wishes of the Association or of the other suitor, however much they might wish to do so. If, then, such changes as are desired can only be effected through the power from which the authority of the University emanates—viz., Parliament,—would it not be more reasonable and economical of time to petition Parliament to grant a Royal Commission to inquire into the working of the University? And this is the more justifiable to ask since the institution is heavily subsidised by the State. Supported by the names of those who are concerned in the various movements, it would be difficult for the Government to refuse the appeal, since it would be in no way casting a reflection upon those who have only too faithfully administered according to their charter, but would be merely an inquiry into the working of what is virtually a State institution, with an authority that no present association, however distinguished, could possibly pretend to, and with this further advantage, that their recommendation when formulated would be more likely to be carried out.

Nothing, to my mind, can be more fatal to the success of those who desire a change in the conduct of the University than to admit for a moment the possibility of another degree-granting power existing in London. To allow such an alternative to be suggested is to court defeat, and would strengthen those who are satisfied with matters as they stand, in their refusal to alter. If this be so, it only remains to bring the existing University into harmony with the desired aims, and this, I believe, can only be done by appeal to its masters.

I am, Sir, yours faithfully,

W. H. ALLCHIN, M.B.,
University Scholar in Medicine.

Chandos-street, W., March, 1885.

CHLOROFORM *v.* ETHER.

To the Editor of THE LANCET.

SIR,—In a communication in your issue of the 7th inst. Mr. George Walker of Liverpool narrates a case of recovery from chloroform narcosis, and institutes a comparison between chloroform and ether, which is to the prejudice of the latter agent. Mr. Woodhouse Braine has taken exception to the statement of Mr. Walker, and warns the profession against the use of chloroform. It appears to me the question is of such great importance that, so far from an apology being needed for those who desire its thorough ventilation, it is a manifest duty for experts to lay all the knowledge and experience they possess before the profession. All who are conversant with the working of our London hospitals know that, as a rule, the majority of students receive no regular instruction in the practice of anæsthetising, and hence few men know the risks they run in private practice when called upon to administer anæsthetics. It is, then, certainly of the last importance that every means be adopted whereby the busy practitioner be kept well abreast of the times in the scientific knowledge of anæsthesia. It is far more common for men in general practice, and especially country practice, to employ chloroform rather than ether. They do so because the apparatus is far simpler, resolving itself into a bottle of the anæsthetic and a towel. In adopting this method but few practitioners contemplate that they are placing the lives of their patients in jeopardy. Again, patients themselves infinitely prefer chloroform. In London, where we habitually induce unconsciousness with nitrous oxide before administering ether, we hear little of the strong distaste patients declare for ether. In the country *tout cela est changé*. There is also a further claim which chloroform has upon the laity. It is the familiar agent to them, and being familiar lacks the awe which the uncanny name of ether provokes. All these reasons tend to induce a far more frequent resort being had to chloroform than to ether, while still another cause leads to the same end. To administer chloroform with apparent success is certainly more easy than to induce narcosis by ether. In the hands of a master of the art like Mr. Braine, the etherisation of a patient becomes to outward semblance a matter of superlative ease; to the tyro it presents pitfalls in practice, and symptoms which, to his 'prentice eyes, assume a truly portentous gravity. The question yet remains, Which agent should be recommended for universal use? Mr. Braine says ether, because (1) mortality from its use is lower than from the use of chloroform; (2) the fatality from ether narcosis is more gradual in development, and so admits of more successful treatment. While most persons conversant with the subject would agree with Mr. Braine, they would possibly suggest that he has not considered the question from every side, and that some of his statements need limitation. It will take a great many arguments to induce a man to relinquish chloroform if he finds that agent more handy, and if he is unfamiliar with the use of ether; yet I agree with Mr. Braine that the choice should, practically, in every case fall upon ether. I would, however, add this, that until ether administration is clearly and systematically taught, I believe its use will never be general, nor its benefits appreciated. I also submit that, as Mr. Braine writes, "dangerous symptoms occasionally arise during the administration of ether," and such symptoms need a far more thorough scrutiny than has as yet been accorded to them. It further must be said, no administrator of ether should lay the flattering unction to his soul that untoward symptoms appear only gradually or recede as soon as the ether inhalation is stopped. The very method which Mr. Braine appears to advocate—the rapid induction of ether narcosis—lends itself to adverse criticism on this score.

If my memory serves me, Mr. Braine, in a paper read before the Medical Society of London, advocated the employment of Ormsby's inhaler. This instrument is open to the objection that it allows a saturated atmosphere of ether to impinge suddenly upon the delicate and sensitive mucous membrane of the larynx and respiratory tract in general, often giving rise to most alarming dyspnœa from spasm of the glottis. This, then, is one of the many dangers to which ether narcosis is liable, and I think it is matter of moment that, while we warn the unwary against the reckless use of chloroform, we should not clothe ether with virtues which its use will speedily repudiate. When nitrous oxide cannot be used, I think and the annals of many years of severe testing in University College Hospital bear out my contention that none of the methods of etherisation can approach that instituted by Mr. Clover, a method alike sound in its scientific basis and convenient for its pre-eminent practicability. Were it competent in this place to consider the question of statistics, it would be my duty to cast some doubt upon the value of such as indicating the relative merits of the two agents, since at present no attempt has been made to arrive at any really accurate return of the number of times ether and chloroform are respectively employed, and of the cases in which death supervenes. Many such cases are not returned at Somerset House as "death from chloroform poisoning." Again, surely "vomiting, nausea, and depression of spirits" are not in many cases trifling ailments. It must occur to all anæsthetists to find persons who evince a peculiar obnoxiousness to ether, and in these many surgical operations could not be performed were ether employed to produce unconsciousness. Nor, again, can straining, sickness, and hiccough, which will every now and again appear, be compatible with the well-being in the post-operation stage of such cases as gastrostomies, &c. Mr. Braine confines himself within such narrow limits that it is impossible for him to do more than offer a very casual glance at the physiological side of the question, and hence it is that his statements, although strictly accurate, yet do not quite cover the whole ground. I may further emphasise the warning given by Mr. Braine by quoting the words of Schiff, the value of whose opinion on this matter can hardly be over-estimated. He says: "Chloroform should be banished from practice as an anæsthetic agent, except in cases in which an extraordinary resistance to the action of ether shows itself."

In conclusion, I would submit that it seems to my mind very doubtful if Mr. Walker is quite accurate in attributing to nitrite of amyl the recovery of his terrier. He employed artificial respiration coëtaneously with the nitrite, and my experience of dogs narcotised with chloroform, which is rather wide, has taught me that artificial respiration, if persevered in for a sufficiently long time, will, in nearly every case, succeed, and if it fails, nitrite fails also. At the same time, as many careful observers have recorded cases which they believe derived benefit from nitrite inhalation, it is unquestionably our duty to try it in every case. The search for amyl nitrite should never, however, be allowed to distract the administrator's attention from performing artificial respiration, which is *the* thing most needful.

I am, Sir, your obedient servant,

DUDLEY W. BUXTON, M.D., B.S.,
Administrator of Anæsthetics in University College Hospital and at the Hospital for Women, Soho-square.
Mortimer-street, Cavendish-square, W., March, 1885.

ELECTRIC ILLUMINATION OF VARIOUS CAVITIES OF THE HUMAN BODY.

To the Editor of THE LANCET.

SIR,—Allow me to complete the information given in my paper on the above subject, and published in your numbers of the 14th and 21st inst., by the statement that incandescent lamps are now manufactured of the same size as those described in my paper, but of a power of eight volts. By using two accumulators coupled together in connexion with these lamps, an illuminating power is obtained which rivals in brilliancy the hydro-oxygen light. [The coupling of the accumulators is effected by connecting the positive pole of the one with the negative pole of the other by means of a small piece of copper wire. The wires connected with the handle of the instrument are then attached to the free poles.] Messrs. Weiss and Son will soon receive a supply of these lamps.

As several letters dealing with the question of warming the laryngoscopic mirror have been recently published in your columns, I wish to state once more distinctly, that the mirror of the electric laryngoscope can be warmed in exactly the same manner as the common laryngoscope—i.e., by holding it over a gas, oil, or spirit lamp, or by dipping it into warm water, *after* it has been attached to the universal handle. No danger of the incandescent lamp cracking or of other accidents happening is to be apprehended.

I am, Sir, yours obediently,

FELIX SEMON.
Welbeck-street, Cavendish-square, W., March 22nd, 1885.

LEACH AND ROOKE MEMORIAL FUND.

To the Editor of THE LANCET.

SIR,—A proposal has of late been made to collect a fund for putting up in our new chapel a window to the memory of Mr. Harry Leach and Dr. Henry Rooke, who were both for many years connected as medical officers with this institution. On behalf of a committee formed by our physicians and surgeons, I beg to bring this project under your notice, and to suggest that we would be pleased to receive any kind help in our endeavour to keep up the memory of these former members of our medical staff, who, during their long association with the Seamen's Hospital, were so widely esteemed.

I am, Sir, yours truly,

W. JOHNSON SMITH.
Seamen's Hospital, Greenwich, March, 1885.

The following subscriptions have been received or promised in furtherance of the fund:—

	£	s.	d.		£	s.	d.
Dr. Robert Barnes, Consulting Physician, Seamen's Hospital	2	2	0	Dr. Robert Farquharson, M.P.	1	1	0
G. Busk, Esq., Consulting Surgeon	2	2	0	W. Johnson Smith, Esq....	2	2	0
Dr. John Curnow, Visiting Physician	1	1	0	John Croft, Esq....	2	2	0
Dr. Robert Carrington, Visiting Physician ...	1	1	0	Gay Shute, Esq....	2	2	0
G. R. Turner, Esq., Visiting Surgeon	1	1	0	Dr. Collingridge	2	2	0
				W. M. Corner, Esq.	1	1	0

MEMORIAL TO DR. FAIRLIE CLARKE.

To the Editor of THE LANCET.

SIR,—Some of the friends of the late Dr. Fairlie Clarke, desirous of evincing their esteem for him, and wishing to perpetuate his memory in some practical manner, have undertaken to erect a drinking fountain in Southborough, where he spent the last eight years of his life. They have come to this decision because among his papers were found plans for a drinking fountain, with the view to the erection of one in this town, and because they feel sure that, to all who knew him, it will commend itself as a suitable memorial. At present donations amounting to £80 have been promised, and if any of your readers would like to subscribe to this fund, subscriptions will gladly be received by the Rev. H. J. Bigsby, Rev. T. A. E. Williamson, General Rowlatt (all of Southborough, Tunbridge Wells), or

Yours faithfully,

H. VERR PEARSON, Treasurer.
Park-road, Southborough, Tunbridge Wells, March 21st, 1885.

LIVERPOOL.

(*From our own Correspondent.*)

THE NEW LYING-IN HOSPITAL.

FOR upwards of forty years there has been in Liverpool a lying-in hospital, and for nearly a century a maternity charity for attending poor married women at their own homes, this latter being known as the Ladies' Charity Each has had its supporters and advocates, while the former has also had its opponents. The new hospital is an honest, and so far a very successful, attempt to give the patients all the benefits of a lying-in hospital without any of its dangers. It consists of two detached cottage hospitals, situated respectively east and west of the central building,

which comprises the rooms for the administrative staff, board-room, kitchen, offices for registration of patients, &c. Each wing is approached from the central building by iron galleries on the ground and first floors, the hospital proper consisting of only two floors. On each floor are three lying-in rooms, each with a single bed and the nurse's room. The whole are so arranged that the nurse can see all the three patients from her room without leaving it. All the sanitary arrangements are admirable, as are also those for securing the thorough cleansing and disinfection of each room after every confinement. Every precaution has been taken to prevent the possibility of contagion. At present patients are admitted without regard as to whether the confinement is expected to be normal or otherwise; but it is probable that the twelve beds will in time be fully required for difficult or complicated labours.

UNIVERSITY COLLEGE.

Dr. Ewing Whittle has resigned the lectureship of forensic medicine and hygiene, which he has held for upwards of twenty years. Among other candidates for the vacancy are Mr. Frank Thomas Paul, Surgical Tutor, late Pathologist and Demonstrator of Physiology; and Dr. James Barr, Visiting Surgeon, H. M. Prison, Kirkdale.

JUVENILE DRUNKARDS.

A boy fourteen years of age was admitted into the Royal Southern Hospital in the afternoon of Sunday, the 15th inst., in an insensible condition. He had been found by the policeman on duty lying in a gutter. Dr. Gordon, the house-surgeon, found him in a state of collapse from alcoholic drinks, and applied the stomach-pump; but it was some time before he was completely restored. It subsequently transpired that the boy reached home late on Saturday night in a state of intoxication, and having slept this off consumed two pints of beer and two glasses of whisky between three and five o'clock on Sunday afternoon. Disgusting though this is, it is only an aggravated example of what is sadly too common in this city in the young of both sexes.

MANCHESTER.

(From our own Correspondent.)

ST. MARY'S HOSPITAL FOR WOMEN AND CHILDREN.

AT the annual meeting of St. Mary's Hospital for Women and Children the cry so common from our medical charities was again heard—expenditure was outrunning income. The charity certainly has special claims, being the only one with a maternity department in the city and neighbourhood, the patients in which during the past twelve months numbered 3045. The cases admitted into the wards were 544, while the total patients under treatment were 14,192. The chairman, Mr. Duncan Matheson, who succeeds the late Canon Bentley, who for so many years was an earnest supporter of the hospital, alluded to the necessity of steps being taken at the earliest possible opportunity to reconstruct or build a new hospital, but the committee were loth to take any further steps in the matter until they could see their way clear to obtaining the funds required for that purpose. It was decided to bring more prominently before the public of Manchester and the surrounding district the work and needs of this particular hospital.

WITHINGTON HOSPITAL.

To the hospital belonging to the Chorlton guardians at Withington additions are shortly to be made, owing to the crowded state of the wards; it was recently stated by one of the members of the Board (a medical man) that it was not safe to perform any serious surgical operation there on account of the overcrowded state of the hospital.

A NEW HOSPITAL FOR INFECTIOUS DISEASES.

At the Crumpsall Workhouse, belonging to the Manchester guardians, plans have been passed for a new hospital for the treatment of infectious diseases, to be erected at a cost of £2400. Hitherto the guardians have sent most of their infectious cases for treatment to the Monsall Fever Hospital. It is certain that, in the event of any serious epidemic in the city, the cases coming under the charge of the guardians could never all be treated and the diseases properly separated the one from the other with the hospital accommodation that can be provided for the above sum.

THREATENED OUTBREAK OF SMALL-POX IN MANCHESTER.

At present we are threatened with an outbreak of small-pox; three deaths were reported last week, a larger number than has occurred for many months; and there are at the present time more cases under treatment than there have been for a considerable time. Scarlet fever, which has been so prevalent for the past eighteen months, appears now to be subsiding; and at the last meeting of the Salford Town Council honorariums were voted for the resident medical officer and matron of the Fever Hospital, of £20 and £10 respectively for the increased work and responsibility thrown upon them during that time.

A NEW PATHOLOGICAL SOCIETY.

A new Pathological Society is about to be formed, which has developed out of the Microscopical Section of the Medical Society. The Microscopical Section was formed some few years ago; but the members have lately felt that its scope of work might be very materially enlarged by adding to it the exhibition and description of pathological specimens—the more so as at the Medical Society's meetings there is always an abundance of contributions of a more strictly clinical character. The founders are actuated by no spirit of opposition or antagonism to the parent Society, but simply desire to work more particularly in a field which they think is neglected, or for which there is not sufficient time and opportunity at the meetings of the Medical Society.

A NEW MEDICAL SOCIETY.

There is a rumour of a new Medical Society being formed by several members of the profession, who object to the meetings and reading rooms, &c., being all located at Owens College, and who have urged the desirability of some more central position. Nothing very definite has, however, yet transpired with regard to this project.

NORTH-WESTERN ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.

At the annual meeting of this Association, Dr. Hime of Bradford was elected president for the coming year. The Society has steadily increased in numbers and influence since its formation some nine years ago, and has had before it for discussion during the past year many subjects of interest and importance from a sanitary point of view. Two subjects which might profitably engage attention, and which are at present before the notice of the public here, are: the pollution of rivers, a Bill respecting which is again before Parliament, and is also a subject at present occupying the attention of the Corporation; and the ship canal scheme from this city to Liverpool, which will require some careful watching in order that provision shall be duly made to prevent the docks, &c., in connexion therewith degenerating into vast cesspools.

PARIS.

(From our Paris Correspondent.)

PROFESSOR BROWN-SÉQUARD ON COCAINE.

AT the last meeting of the Société de Biologie, Professor Brown-Séquard read a note on the local analgetic action of cocaine, which he looked upon as a new example of inhibitory action. Experiments performed by the author proved that cocaine acted through the medium of the peripheric nerves on the nervous centres, which react in producing an inhibition of sensibility. The phenomena which result from the injection of a certain quantity of cocaine at the level of the larynx are absolutely the same as those which are consecutive to the application of a jet of carbonic acid on the mucous membrane of the larynx. Two minutes after this injection there is a generalised anæsthesia and an analgesia of the different wounds made on the body of the animal. The cutaneous anæsthesia lasts only a few minutes, but the analgesia of the wounds persists even till the following day. If fresh wounds are made, these, far from being analgetic, become, on the contrary, hyperalgetic. That which proves that cocaine acts on the nervous centres, and particularly on the cerebellum, is that the injections of this substance produce sometimes a rolling motion to the side opposite to the injection, and at others a turning motion. Evidence of the inhibitory action may be obtained by another experiment: when the dose

of cocaine injected has been large enough to produce convulsions, it is sufficient to pull or forcibly flex the toes to immediately stop the convulsions. In animals which die under these conditions the author found the temperature of the body after death as high as 44·4° C., or 111·6° F.

THE ADJUNCTION OF CHLOROFORM AND COCAINE.

Dr. Ferrier lately read a report before the Surgical Society of Paris on a work by Dr. Dransart, who proposed the adjunction of chloroform to cocaine for operations on the eye. The chloroform is administered in the usual way after an instillation of cocaine, and the time taken up to administer the former is thus reduced to one or two minutes. The advantages claimed for this method are that the deeper tissues of the eye, such as the iris, muscles, optic nerve, &c., may be cut into without causing pain, which would not be the case with the instillation of cocaine alone. The duration of chloroformisation being considerably reduced, the dangers attending the administration of chloroform are *pro tanto* diminished.

VASELINE IN PASTRY.

At a recent meeting of the Council of Hygiene and of Salubrity of the Department of the Seine, M. Alfred Riche read a report concerning the employment of vaseline in pastry as a substitute for grease or butter. The reporter stated, in the name of the commission charged to investigate the matter, that however advantageous the use of vaseline may be to vendors of pastry, inasmuch as it prevents the latter from becoming rancid, it is nevertheless, used for that purpose, injurious to health. Moreover, as vaseline does not possess the nutritive qualities of fat or butter, and as the action of the derivatives of petroleum on the economy, particularly on the digestive apparatus, is as yet but little understood, the council have recommended the interdiction of the employment of vaseline for alimentary purposes.

Paris, March 24th.

NEW YORK.

(From a Correspondent.)

So many contradictory statements have been made regarding the nature of the disease with which the veteran General Grant, ex-President of the United States, is afflicted, that I thought your readers would like some authentic report on the subject. For this purpose I visited Dr. George R. Elliott, of 105, Madison-avenue, who has made microscopic preparations of the morbid growths removed from General Grant's throat and examined them at his leisure. The following is his report written for THE LANCET at my request:—

"The disease is not extensive, the ulcerations being limited to the right pillars of the fauces, the anterior one being perforated near its base. The adjoining side of the tongue is but slightly indurated, as is also a neighbouring gland. The case being somewhat unique in its development and progress, a microscopical examination of a small portion of the growth was deemed advisable as an aid in arriving at an exact diagnosis. General Grant readily consented to the removal of a piece for this purpose, and a portion about the size of a pea was taken from the ulcerated edge by Dr. F. C. Riley at the request of Dr. J. H. Douglas. This specimen was rapidly hardened in alcohol, and at the end of thirty-six hours sections were made, stained and mounted for examination. The following histological findings were readily made out:—The structure is largely composed of epithelial tissue, which in places appears in the form of distinct lobules. In portions of these lobules the cells are grouped into concentric globes or cell-nests. The individual epithelial elements present great multiformity in shape, and lie in close contact with each other. Marked evidence of cell proliferation is seen in the deeper layers of the specimen. There is a more or less complete stroma or framework running through portions of the growth, composed of fibrous tissue rich in small round cells. By way of summary, thus: the more or less lobulated appearance of the epithelial mass, the grouping of the epithelial elements into concentric globes, the great diversity in the shape of the cell elements, the evidence of cell proliferation and the peculiar arrangement of the stroma, would warrant a diagnosis of epithelioma of the squamous variety. The specimen was removed on February 18th, 1885, and the report submitted on February 23rd. The diagnosis was arrived at only after the greatest possible care had been taken to exclude all sources of error, with a full knowledge of the clinical history and with a mind anxious to find only the microscopical evidence of a benign or innocent growth. After rendering the report the specimens were shown to Dr. T. E. Satterthwaite, the well-known pathologist, who fully confirmed the diagnosis. Upon request they were also exhibited to the eminent gentlemen of the consulting staff—viz., Drs. Fordyce Barker, H. B. Sands, J. H. Douglas, and G. F. Shrady."

With this detailed report you will, doubtless, be in a position to draw your own conclusions as to General Grant's condition. My own impression is, after a careful examination of the microscopical preparations and consultation with Dr. Elliott, that there is nothing in the nature of the disease that is likely to kill General Grant at an early date, although the failure of his general health may precipitate a crisis at any time. Stimulants do not act kindly, and cocoa only has been administered with success. Still, if the general tone of his system could be maintained, his naturally strong constitution may enable him to combat the ravages of the disease for some time. If an early fatal termination of the case should happen, it will probably be due to the invasion of his sick room by some half-dozen physicians, and reading the exaggerated reports which are daily printed in the public press.

VIENNA.

(From our own Correspondent.)

SMALL-POX IN VIENNA.

SPORADIC cases of small-pox have occurred in Vienna every week for years, but during the last few weeks a progressive increase of such cases has been noticed. While their number amounted formerly to from 10 to 15 weekly, 13, 14, 30, 46, 43, 46, 41, 59, 64, and 96 cases have been reported in each respective week of the present year. In the western suburbs of the city the cases of small-pox have become so numerous (the latest return being 108) that several schools have had to be closed. It is noteworthy that the disease has attacked unvaccinated individuals for the most part, and that the deaths occurred exclusively in that class, and in the aged, on whom the effect of vaccination may have disappeared. In Vienna only 16 cases proved fatal during last week.

A CASE OF AGRAPHIA WITHOUT APHASIA.

It has been contended that agraphia without aphasia is possible, and the following case, which occurred on the 10th inst. in the clinique of Professor Rosenthal at the Vienna Allgemeines Krankenhaus, may contribute to the solution of the question. A widow, aged forty-five, who, as she stated, had never been ill before, was attacked about three weeks ago with hemiplegia of the right side, which slowly improved. Paraphasia seemed to have supervened, the patient confounding the less common words. Eight days ago the patient, who formerly maintained a lively correspondence, perceived that she was unable to read and to comprehend words, although she could, with some difficulty, spell the letters; nor was she able to write words, while she could quickly write as well as read figures and numbers. Without effort she can read special words—for instance, her name, Anna, and that of her late husband, Johann, even if these names are written badly and in small characters. Examination with the ophthalmoscope showed only a considerable hypermetropia and a right hemianopia.

ADDISON'S DISEASE.

The typical example of this disease is composed, as is well known, of three chief groups of symptoms:—(1) Anæmia and asthenia; (2) dark discolouration of the skin; and (3) disorder of the digestive apparatus. Professor Nothnagel considers the second symptom as the first in importance, the asthenia occupying the second place, while he regards the anæmia as of much less moment. According to numerous histological researches the discolouration is caused by an intense pigmentation of the deepest layers of the rete Malpighii. Several years ago

Dr. Ehrmann of Vienna proved that in the amphibia the pigment does not originate in the epidermis cells, but in those of the cutis; he and Dr. Riehl stated also that the hair derives its pigment from the cutis. Virchow, too, some years ago found in cases of Addison's disease pigment cells not only in the deepest layers of the rete Malpighii, but also in the uppermost layers of the cutis—namely, along the nerves and vessels. Nothnagel likewise observed numerous pigmented cells in the uppermost layers of the corium of the skin of negroes. From these facts he concludes that the pigment does not originate in the deepest layers of the rete Malpighii, but is carried into the epidermis by the pigment cells. According to his views the pigment owes its origin to the blood, from which it issues already dissolved, a process which resembles the pigmentation noticed by a French observer in connexion with the spawn of frogs. Like the majority of inquirers, Professor Nothnagel supposes that it is probably due to an affection of the large nervous apparatus of the sympathetic. Also in cases of other diseases a pathological pigmentation is caused by affections of the retro-peritoneal region. Contrary to the statements of Jürgensen, in the last observed case of Addison's disease the medullary, as well as the non-medullary, fibres of the splanchnics were unaltered. The patient died, as usual, comatose. In the urine much acetone was found. Nothnagel expressed an opinion that the coma is probably caused by acetonuria, and not exclusively by anæmia of the brain.

SWALLOWING ARTIFICIAL TEETH.

Two cases of the above nature have lately been treated in the wards of Professor Billroth. A woman, living near Vienna, swallowed during the night of January 28th an artificial set of teeth, which she omitted to remove from her mouth before retiring to rest. All endeavours to extract the plate from the œsophagus, where it lodged, failed until she came under the care of Professor Billroth, who removed the foreign body by œsophagotomy. Symptoms of commencing gangrene of the œsophagus appeared, and a fatal result was feared. A part of the operation wound had been left open for the insertion of a drainage-tube as far as the stomach, and the entire wound covered with iodoform gauze. After a lapse of eight days the drainage-tube was removed, and in another week the wound had closed. The patient is now perfectly well; stricture did not occur. The second case was that of a girl aged nineteen, who swallowed a set of teeth during the night of Feb. 14th. All endeavours to extract the plate were vain. On admission to hospital the foreign body could distinctly be felt in the œsophagus. On the following morning the largest sound could easily be introduced, and Prof. Billroth decided to perform gastrotomy about three centimetres below the edge of the ribs on the left side. Through an incision in the stomach he tried ineffectually to reach the foreign body with the finger; he then drew out almost the whole of the stomach, but without discovering the object of his search. Although it was improbable that the plate had passed the pylorus, he enlarged the wound in the abdomen and explored the abdomen with his hand, but again without success. Only that part of the stomach remained to be searched which is fixed to the spleen. Here Professor Billroth, introducing his other hand, found the body lying flat against the wall. The stomach was sewn up, put back, and the wound in the abdomen was likewise closed. The patient is already able to take liquid nourishment.

Vienna, March 19th.

MEDICAL NOTES IN PARLIAMENT.

The Poisons Bill.

IN the House of Lords on the 22nd inst., the Earl of Milltown gave notice that on the motion to go into Committee on the Poisons Bill he will move that it be referred to a Select Committee.

The Lunacy Bill.

On the 26th inst., the Lord Chancellor, in presenting a Bill to Amend the Lunacy Laws, said there were two classes of lunatics—Chancery lunatics and those confined in different places of care throughout the country. Chancery lunatics were comparatively few in number, not exceeding 3000 or 4000 cases, and it was not proposed to alter to any considerable degree this branch of the law, except that on one or two points some extension of the powers of the Court of Chancery was suggested. He might here point out that it would be a very desirable thing to consolidate the various Acts which deal with lunacy, and a Bill was actually prepared with that object, but it was deemed advisable to postpone its introduction until it was seen what change would be effected by the measure he was now bringing before their lordships. Premising that it was an honest and carefully considered attempt to deal with the subject, he admitted that there were points in it on which considerable differences of opinion existed, and on one very important provision he regretted that the proposition he had to recommend to the acceptance of the House was opposed by Lord Shaftesbury and his colleagues on the Lunacy Commission. The Bill did not deal with the administrative establishments, either of Chancery or the Lunacy Commissioners, which had worked well and proved satisfactory. He did not say that some change might not be necessary in them, but as they formed a collateral branch of the subject it was not necessary to encumber the measure with any clauses dealing with them. As the law at present stood with regard to the initial steps for a commitment in lunacy, it was possible that an opinion might be obtained, perfectly honestly, from two medical gentlemen, who had to sign the certificate, upon insufficient grounds and not of that absolutely impartial and disinterested character which was desirable. It might be that abuses had taken place in that way. In Scotland a person could not be confined as a lunatic on the authority of a private individual. The practice was to present a petition to the sheriff, accompanied by a statement of the particulars of the case, supported by the certificates of two medical practitioners, on the strength of which an order could be made for the reception of the lunatic into an asylum. If the sheriff was not satisfied with the certificates he could make independent inquiry. The Scotch law also provided means for dealing with cases of urgency without delay, and similar provisions existed in the legal system of most civilised countries. The committee of 1877 reported against the introduction of like powers into the law of England; but although Lord Shaftesbury was still adverse to the principle, those who were responsible for the present measure had been induced to recommend its adoption, attended by precautions to prevent its unguarded application. As to cases of the ordinary character, it was proposed that no person, not a pauper or found lunatic by inquisition, should be detained in an asylum, hospital, or licensed house without an order under the hand of a county court judge, a stipendiary magistrate, or a justice of the peace possessing the necessary jurisdiction. The petition was to be supported by the certificates of two medical men, one of whom must, if possible, be the ordinary medical attendant of the patient. No advantage would be gained by requiring a statutory declaration from the medical man, and there would be the disadvantage of multiplying the applications to magistrates; but if the certificate contained any material statement that was false to the knowledge of the medical man, he would be subject to the same penalties as in the case of a statutory declaration or statement on oath. If the magistrate was satisfied with the evidence of the lunacy contained in the medical certificate, he would be empowered to at once make the order; but if he was not satisfied, he could direct a further investigation. That inquiry would be conducted in private, and those necessarily present would be bound to secrecy, unless required by lawful authority to divulge what had transpired. If the magistrate thought it desirable to dismiss the petition, he must give his reasons in writing for doing so. It would thus be perceived that the framers of the measure had been most anxious to prevent the evils anticipated by those who objected to the introduction of a magistrate. Not only had better securities been provided with regard to initial steps in cases of lunacy, but it was proposed that every order should be limited in its duration to three years, unless at the end of that period the proper medical authorities certified that the patient ought to be detained, in which case the order might be renewed from year to year. Among the other provisions of the Bill, there was one giving to the Crown generally a power which it did not at present possess—to initiate prosecutions in all offences against the Lunacy Laws. Power, too, was given, where it should appear that a lunatic could manage his person but not his property, for the appointment of a committee to manage his estate and suspend interference with his person. The important part of the Bill was that relating to licensed houses or asylums. A great objection had been frequently made to such houses, on the ground that it was inexpedient that any person should have a pecuniary interest in the

continued detention of an insane person. The subject was undoubtedly one of great importance, and also of great difficulty. It was therefore proposed to give greater facilities for extending the asylums system, so that it might by degrees be adopted for the general reception of private and non-pauper patients. The county and borough justices would be given the power to provide separate treatment for particular classes of patients, and in addition it was proposed that the Home Secretary should have in respect of private patients the same powers he now enjoyed as to pauper lunatics. It was hoped, therefore, that the system of public asylums would become in a natural way a substitute for these licensed houses. At the present time, and looking to the great number of patients in licensed houses, their sudden absorption did not seem wise or desirable. There were provisions in the Bill for the compulsory purchase of licensed houses upon terms to be fixed by the Act, the amount to be ascertained by a jury or by arbitration; but to suppress these houses, on which a large outlay had been made, and to do it suddenly, without having in the meantime made adequate provision for the large number of lunatics to be dealt with, was a step which could not be recommended. No new licences, however, would be granted after the passing of the Act without the consent of the Secretary of State.

The Bill was then read a first time.

The Condition of the Thames.

In the House of Commons, on the 19th inst., in reply to Mr. Labouchere, who asked the Secretary of State for the Home Department whether any action was contemplated in view of the deputation from the Local Board of Twickenham, which recently waited upon him to call attention to the condition of the Thames between Richmond and Isleworth, Mr. Fowler stated that there was some conflict as to whom the authority for the work lay upon. Some contended it was the Metropolitan Board of Works who were responsible for sewage works, and others that it was the Thames Conservancy Board who had jurisdiction over the work of removing the mud. No time, however, would be lost to remedy the present state of things, which was a disgrace to the Thames.

The Reception of Insane Persons into Workhouses.

Mr. J. Talbot asked the Secretary of State for the Home Department whether his attention had been called to a report of a case at the Westminster Police-court, according to which an alleged lunatic was refused admission to the workhouse, "a course which was adopted, it was stated, in consequence of a recent legal decision." Sir W. Harcourt replied that in his opinion the man ought to have been admitted to the workhouse. Nothing could be more undesirable than that an alleged lunatic should be sent to prison. He was much surprised at the alleged decision, although there was doubtless some obscurity in the law. The fact was that the guardians would not admit, not that they could not.

On the 24th inst. Mr. G. Russell, replying to Lord Algernon Percy, said that the Guardians of the Westminster Union have called the attention of the Board to the decision of Mr. Justice Wills in the Marylebone case. It appears that in that case a woman, who was not a pauper, and who was alleged not to be under proper care and control, was by stratagem removed to the workhouse, and was detained there against her will for a period of fourteen days, and that the requirements of the statute were altogether ignored. The publicity which has been given to the decision in this case will be a warning to the officers of other unions if there should be any disposition to adopt a similar course. It does not at present appear to the Board to be necessary to issue a circular letter on the subject, neither would they be prepared to propose legislation for legalising action such as that in the case in question.

Small-pox in Egypt.

On the 23rd inst., the Marquis of Hartington, in reply to Mr. Hopwood, said that since the first arrival of the British Army in Egypt up to the latest returns, eighty-one cases of small-pox had occurred amongst the troops, including those on the Nile and at Suakim. Of that number seven had proved fatal. The regulations as to revaccination had been satisfactorily carried out.

Public Health Act.

On the 25th inst., a new Bill by Sir J. Kennaway to amend the Public Health Act, 1875, with respect to members and officers of local authorities was, by leave, brought in and read a first time.

Obituary.

CHARLES PALMERSTON TURNER.

THE announcement of the death of Surgeon Turner, which appeared in our issue of March 15th, will have been read with sorrow and regret by many members of the Medical Staff Corps, as well as by a large circle of friends.

Surgeon Turner entered the army in 1874, and had seen a great deal of service. Three years after he entered the service he took part in the expedition against the Gowaki Afreedees with the 51st Light Infantry; he was also employed in the Afghan war of 1878-79, and was present at the assault upon Ali Musjid, being mentioned in despatches. In the Egyptian war of 1882 he was at the battle of Tel-el-Kebir, and in 1884 he was present at the battles of El-Teb and Tamai, in the former of which he was slightly wounded. He received the various medals awarded for these expeditions, and, in addition, the Egyptian Bronze Star. Surgeon Turner was among the first who were ordered to Egypt on the outbreak of cholera. In the early autumn of last year he returned to England on six weeks' private leave; but before his leave had expired he was ordered back to take part in the Nile expedition for the relief of Gordon, when he was attached to the 19th Hussars. He was present at the battles of Abu Klea and El-Gubat, and was with General Buller's force in his retreat across the desert. He was brought into camp at Korti by a party of Hussars on March 5th, and died of enteric fever on the following day. His professional efficiency, his happy indifference to privation and hardship, his unselfish character, his frank and open countenance and mode of conversation caused him to be respected by all, and much beloved and esteemed by those who were more closely associated with him. Though much pressed for time when he was preparing for his departure to take part in the Nile expedition, one of his last acts before leaving was to visit one of the military hospitals to see a patient who had expressed an earnest wish to see him, and upon whom he had performed double amputation after the battle of El-Teb. He leaves behind him, besides many sorrowing friends, two sisters and an aged mother, his tender consideration for whom was only one among the many charming points in his character. Truly this unhappy struggle is costing England the lives of some of the best and bravest of her children.

Medical News.

COLLEGE OF PHYSICIANS IN IRELAND.—At the examinations held this month the following obtained the licences in Medicine and Midwifery of the College:—

MEDICINE.—George Brown, George Fletcher Collins, John Hobbs, George St. John Oldham, Robert John Langford Rowley.

MIDWIFERY.—Anthony Lawrence Blake, George Brown, Geo. Fletcher Collins, John Hobbs, George St. John Oldham, Robert John Langford Rowley.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—At an examination held on March 9th and 10th the undermentioned Licentiate was admitted a Fellow of the College:—

David Edgar Flinn.

THE Library of the Royal Medical and Chirurgical Society will be closed from Good Friday to Easter Monday, both days inclusive.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on the 19th inst., the degree of Bachelor of Medicine was conferred on Charles Slater, St. John's.

MR. RICHARD BENYON, of Englefield House, near Reading, has just given £1000 to the funds of the Royal Berkshire Hospital, of which he is President.

A WELL-ATTENDED public meeting, called by the National Society for Securing Effective Legislation against River Pollution, was held on 25th inst. at the Mansion House.

ITALIAN UNIVERSITY DISTURBANCES.—The students of Rome, Bologna, Pavia, Pisa, and Naples have passed resolutions refusing to attend any lectures until amends have been made by the Ministry to the Turin students who were attacked by the police on the occasion of a recent demonstration, some bloodshed ensuing.

THE East Ham Local Board have represented to the Barking Sanitary Authority the desirability of having an infectious diseases hospital, suggesting a combination for the purpose.

THE Mary Fletcher Hospital of Burlington, Vermont, receives nearly $200,000 by bequest of Miss Mary A. Fletcher, who has just died in that city. The bequest comprises nearly her whole estate.

THE Royal Zoological Society of Ireland will, during the visit of H.R.H. the Prince of Wales, give a conversazione at the Royal College of Surgeons in Ireland, by permission of the Council of the latter institution.

HOSPITAL SUNDAY for Chatham and neighbourhood is fixed for April 19th. The ministers of more than sixty churches and chapels have promised to have collections. The Secretary is the Rev. D. Cooke, Vicar of Brompton.

THE "Sydney Morning Herald" states that the prize of £100, offered last year by the New South Wales Linnæan Society for the best essay on "The History of the Bacillus of Typhoid," is again announced as open to competition upon the same conditions as before.

TUNBRIDGE WORKHOUSE INFIRMARY.—The Local Government Board has authorised the Tunbridge guardians to erect a new infirmary at the workhouse, in accordance with the plans submitted, at a cost not exceeding £5000. Permission has been given to borrow the amount.

AT a meeting of the members of the Anthropological Institute held on the 24th inst., a paper was read by Mr. A. J. Duffield on "The Inhabitants of New Ireland and its Archipelago." Mr. R. Brudenell Carter and Mr. C. Roberts read papers on "Vision Testing."

THE sub-committee appointed to confer with the superintendent of the Aberdeen Infirmary respecting fresh regulations for the admission of visitors to that institution have reported in favour of the adoption of a system under which the friends of each patient would be supplied with a ticket to admit two, and which would be transferable. The recommendation was approved of.

ABERNETHIAN SOCIETY. — The annual general meeting of this Society for the election of officers took place on the 19th inst., the result of the ballot being as follows:—Presidents: Dr. E. W. Roughton and Mr. W. T. H. Spicer. Vice-Presidents: Mr. C. P. Crouch and Mr. A. Lyndon. Honorary Secretaries: Mr. F. W. Andrewes, and Mr. T. W. Gardner. Additional Committeemen: Mr. Colby and Mr. A. R. Farrar.

EXTENSION OF BOOTLE HOSPITAL.—A meeting of the working men of Bootle and neighbourhood was held on the 19th inst., to consider the best means of assisting in the effort being made for the extension of the borough hospital, by the founding and maintaining of a working men's ward. It was unanimously resolved, after some discussion, that funds should be raised sufficient to build and fit up such a ward.

ESSEX AND CHELMSFORD DISPENSARY AND INFIRMARY.—The committee of these institutions report that in the dispensary the cost of each patient has been about 6*s.*, including the gratuities to the medical officers (25 guineas to each of the three), rates, taxes, and all other expenses; while the cost for drugs, &c., has been about 3*s.* per head. In the infirmary in 1884, 104 patients were admitted, and the expense of each patient has been about £3 17*s.*

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.—On Tuesday, the 10th inst., the thirty-sixth annual report of the Wolverhampton and Staffordshire Hospital was submitted to the governors and subscribers. The number of in-patients treated during the past year has been 1899, as against 1731 in the preceding year, of which 962, as accidents or urgent cases, were admitted without tickets. The excess number consists of 53 adults and 115 children; and the total number includes 138 cases of fever or other infectious disease treated in the fever wards, 34 cases in the ward for the treatment of diseases of women, and 358 children under ten years of age treated in the children's ward. The average daily number of in-patients has been 116, the cost per head £2 16*s.* 8*d.*, and the average stay in the hospital twenty-three days. The number of out-patients during the past year has been 11,597, showing an increase of 920 as compared with the preceding year, of whom 4155, as accidents or urgent cases, were treated without tickets. The cost per out-patient has been 1*s.* 8¾*d.* Forty-five patients have been sent to various convalescent institutions. The Hospital Saturday collections amounted to £2381 14*s.* 10*d.*, an increase over last year of £132 12*s.* 7*d.*, the largest amount collected in one year since the adoption of Hospital Saturday in 1874. The amount received from the Hospital Sunday collections was £697 18*s.* 9*d.*, being an increase of £39 8*s.* 7*d.* over the year before. During the year, to meet a deficiency in the accommodation for women suffering from diseases requiring surgical treatment, two houses were taken upon lease and converted into a special hospital, to contain five patients, each to have the comfort and privacy of a separate room. The necessary outlay has been met by donations from generous friends.

SAD DEATH OF A "LADY DOCTOR."—A sad story comes from Chicago of the death of an English baronet's widow, who had been striving to keep herself by medical practice. She was a graduate of the Rush Medical College, but seems to have been unable to earn sufficient to live upon, and when she died suddenly of apoplexy she was looked upon as a pauper; some papers were, however, found which gave an indication as to her history, and enabled funds to be obtained by which her funeral expenses were met.

PRESENTATION. — Dr. William Richardson, of Shepherd's-bush, who has for many years practised in the district, having retired from the active duties of his profession at the beginning of the present year, was presented on Thursday evening, the 12th inst., with a testimonial by his numerous patients. It consisted of a silver gilt dessert service of four pieces, one centre-piece and three fruit dishes, richly ornamented, with a suitable inscription engraved upon them. A travelling writing-case handsomely fitted, and an illuminated album containing the signatures of the subscribers, accompanied the testimonial.

HOSPITAL FOR SICK CHILDREN.—The thirty-third anniversary festival of the Hospital for Sick Children, Great Ormond-street, was held on Wednesday night last, when Earl Rosebery presided. Amongst those present were Viscount Gort, Lord Aberdare, Sir James Paget, Rev. Robert Milner, Dr. Dickinson, and Dr. Gee. The speeches of the noble lord and of Sir James Paget were frequently applauded. Dr. Cheadle, the senior physician to the hospital, replied to the toast of the medical officers of the institution. During the evening subscriptions and donations amounting in the aggregate to £1267 were announced.

SELLING AN INFECTED BED.—A dustman has been summoned at the Yarmouth Police-court, under the 126th Section of the Public Health Act, for selling a bed which had been in contact with infectious disease. The Town Clerk prosecuted. A typhoid patient had died on the bed, which was very much stained, and the doctor in attendance said that it must be destroyed. The defendant was given a shilling to destroy it, but instead of doing so he sold it for a shilling to another man, who afterwards found means of reselling it for £1. The magistrate said it was a bad case, and fined the dustman £1 and costs or a month's imprisonment, and the man who received it from him £2 and costs or a month's imprisonment.

Medical Appointments.

Intimations for this column must be sent DIRECT *to the Office of* THE LANCET *before 9 o'clock on Thursday Morning at the latest.*

BASSETT, H. THURSTAN, M.B.Lond., has been appointed Surgeon to the Birmingham and Midland Skin and Lock Hospital, vice J. W. Taylor, F.R.C.S.Eng., resigned.

BRAMWELL, ERNEST, M.D.Aber., M.R.C.S., L.S.A.Lond., has been appointed Medical Officer to the Workhouse of the Tynemouth Union, vice J. W. Bramwell, resigned.

BROWNE, GEORGE HENRY, L.R.C.P.Ed., L.F.P.S.Glas., has been appointed Medical Officer of Health for the Brynmawr Urban Sanitary District, vice Skrimshire.

CHURCHILL, JOHN FOOT, L.R.C.P.Lond., M.R.C.S., L.S.A.Lond., has been reappointed Medical Officer and Public Vaccinator for the Second District of the Amersham Union.

EDWARDS, FREDERICK SWINFORD, F.R.C.S.Eng., L.R.C.P.Lond., has been appointed Assistant-Surgeon to St. Mark's Hospital for Diseases of the Rectum.

EVANS, JOHN, M.R.C.S., L.S.A.Lond., has been appointed Medical Officer for the Ely Schools, Cardiff Union, vice Sheen.

HUGHES, Mr. THOMAS, has been appointed Public Analyst for the Borough of Newport, Monmouthshire.

IRWIN, JAMES ROSS, L.R.C.P., L.R.C.S.I., has been appointed Medical Officer to the Workhouse, and to the Whitehaven and Preston Quarter District of the Whitehaven Union, vice Wilson, resigned.

JACKSON, THOMAS, L.R.C.S.Ed., L.S.A.Lond., has been appointed Medical Officer for the Holbeach North District of the Holbeach Union, vice Harper.

KEYWORTH, JOHN WHITE, M.D.Lond., M.R.C.S. (of Wellington, New Zealand), has been appointed Surgeon-Superintendent of the Napier Hospital.

MATHESON, FARQUHAR, M.B., C.M., has been appointed Honorary Aurist to the Royal Caledonian Asylum, Holloway, N.

MCGEAGH, JAMES PAUL, M.D., M.Ch.Q.U.I., has been appointed Medical Superintendent to the Mill-road Infirmary, West Derby Union.

PENRICE, DAVID SIMPSON, M.R.C.S., L.S.A.Lond., has been appointed Medical Officer for the Fourth Norwich District and Boys' Home, vice T. W. Richardson.

PRIEST, J. DAMER, M.R.C.S., L.S.A.Lond., has been appointed Medical Officer of Health for the Urban Sanitary District of Waltham Holy Cross.

WALLER, CHARLES B., M.R.C.S., L.S.A.Lond., has been appointed House-Surgeon to the Rotherham Hospital and Dispensary, vice Garrard, resigned.

WILLIAMS, E. R., M.R.C.S., L.R.C.P.Lond., has been appointed Senior House-Surgeon to the General Infirmary, Macclesfield.

Births, Marriages, and Deaths.

BIRTHS.

LANGFORD.—On the 22nd inst., at Park House, East End, Finchley, the wife of Dr. Phineas Pitts Langford, of a daughter.

SILK.—On the 23rd inst., at Victoria House, Highgate-hill, N., the wife of J. Fredk. W. Silk, M.D.Lond., of a daughter.

WARWICK.—On the 18th inst., at Halesworth, Suffolk, the wife of Percy Warwick, L.R.C.P.Lond., M.R.C.S., of a daughter.

WIGMORE.—On the 15th inst., at Twerton-on-Avon, Bath, the wife of J. Wigmore, M.D., of a son.

MARRIAGES.

DIXON—AUSTEN.—On the 25th ult., at St. George's Church, Ramsgate, Walter Dixon, M.B., C.M., of Shepherd's Well, to Flora, daughter of the Rev. E. T. Austen, of Barfreston Rectory, Kent.

GOULD—LUSH.—On the 24th inst., at Regent's-park Chapel, by the Rev. W. Landels, D.D., of Edinburgh, and the Rev. G. P. Gould, M.A., of Bristol, Alfred Pearce Gould, M.S., F.R.C.S.Eng., of Queen Anne-street, W., to Florence, youngest daughter of the late Right Honourable Lord Justice Lush.

GUINNESS—MARKS.—On the 23rd inst., at St. Mark's, Hamilton-terrace, Thomas Archibald Guinness, M.R.C.S., of Bampton, North Devon, son of Arthur Hart Guinness, Esq., of Greville-place, Maida-vale, N.W., to Edith, younger daughter of H. Stacy Marks, Esq., R.A., of Hamilton-terrace, St. John's-wood.

DEATHS.

CAIRD.—On the 1st ult., at Hartwell House, Kiama, New South Wales, John Hay Caird, L.R.C.S.Ed., & J.P., second son of James Caird, Farskane, Cullen, Banffshire, aged 29.

COATES.—On the 25th inst., at Endless-street, Salisbury, William Martin Coates, F.R.C.S., aged 73.

FOULDS.—On the 12th inst., at Chesterfield, Samuel Foulds, M.R.C.S., L.R.C.P.Lond., Hon. Surgeon to the Chesterfield and North Derbyshire Hospital, aged 50.

JOHNSON.—On the 18th inst., William Henry Johnson, Surgeon, aged 66.

KINGSLEY.—On the 18th inst., at Church House, Stratford-on-Avon, Henry Kingsley, M.D., in his 67th year.

MASON.—On the 18th inst., Samuel Mason, Ext. F.R.C.P.L., M.R.C.S., F.R.G.S., of Lewisham High-road and Finsbury-circus.

MITCHELL.—On the 15th inst., at Rhynie, Aberdeenshire, Alex. Gordon Mitchell, M.B., C.M.Aber., aged 41.

TUCK.—On the 24th Jan., at Tambo, Queensland, Australia, John Tuck, M.R.C.S., aged 42.

N.B.—*A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.*

Medical Diary for the ensuing Week.

Monday, March 30.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10.30 A.M. each day, and at the same hour.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M. each day, and at the same hour.

ST. MARK'S HOSPITAL.—Operations, 2 P.M., and on Tuesdays at the same hour.

HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.

METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.

ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.

MEDICAL SOCIETY OF LONDON.—8.30 P.M. Mr. Walsham: On the Treatment of Caries of the Spine in the Upper Dorsal and Lower Cervical Region by a Combined Jacket and Collar of Porous Felt.—Dr. Woakes: On Necrosing Ethmoiditis, and its Relation to the Development of Nasal Polypus.

Tuesday, March 31.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at the same hour. Ophthalmic Operations on Mondays at 1.30 and Thursdays at 2 P.M.

ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.

CANCER HOSPITAL, BROMPTON.—Operations, 2.30 P.M.; Saturday, 2.30 P.M.

WESTMINSTER HOSPITAL.—Operations, 2 P.M.

WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—8 P.M. Adjourned Discussion on Cholera.

Wednesday, April 1.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.

MIDDLESEX HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.—Ophthalmic Operations on Tuesdays and Thursdays at 1.30 P.M.

ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Skin Department: 9.30 A.M., on Tuesdays and Fridays.

ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.

LONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.

GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Saturday, 2 P.M. Skin Department: 1.45 P.M.; Saturday, 9.15 A.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 3 to 4 P.M.

OBSTETRICAL SOCIETY OF LONDON.—8 P.M. Specimens will be shown by Dr. John Williams and others.—Dr. Murphy: Sequel to a case of Ovariotomy.—Dr. John Williams: On the Circulation in the Uterus, with some of its Physiological and Pathological Bearings.—Dr. Bousquet: Note sur un cas d'Absence Totale de l'Utérus et d'Occlusion du Vagin.—Dr. W. H. Day: Case of Uterine Fibroid complicating Labour treated by Enucleation.

Thursday, April 2.

Friday, April 3.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1.30 P.M.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.

Saturday, April 4.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editor."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe, or recommend practitioners.

Local papers containing reports or news-paragraphs should be marked.

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

M.R.C.S.—1. We think B. though perhaps within his strict rights in refusing to meet our correspondent, would have acted more properly in agreeing to a consultation.—2. A practitioner has a right, perhaps, as we have said, to refuse to meet another in consultation; but for doing so he should have very good grounds indeed, of which the chief must be moral grounds. Fine questions of age are not sufficient, young men and older ones having each their advantages, and being able to render each other and the patient different kinds of service.—3. If one practitioner refuses to meet another, the other is at liberty, if requested to do so, to take the case.—4. It would be returning evil for evil to refuse to do so.—5. Yes.

Puzzled.—Mr. Upcott Gill, Strand, London, publishes a "Guide to the Medical Profession."

"CARBOLIC OIL A REMEDY AGAINST MOSQUITOES."

To the Editor of THE LANCET.

SIR,—*A propos* the letter on the above subject in your last issue, I may say I have been in India a number of times and have had some experience of these troublesome insects, and have tried several remedies (so-called) upon myself and other Europeans, and among them carbolic oil, 1 in 15, which I verily believe rendered them more troublesome. For the very annoying after-itching, which sometimes comes on every night for a week or more, or until one has been out at sea a day or two, I tried mango juice and also concentrated solution of acetate of ammonia, which was recommended by a Calcutta chemist, but with slight effect. What mosquitoes really do dislike is cocoa-nut oil, which is decidedly useful, but has an objectionable odour. Ladies in India suspend a small sponge, with a few drops of oil of lavender, above the heads of their sleeping infants with some good effect.

Believe me, Sir, yours truly,

JOHN C. UNDERWOOD,
Ashford, Kent, March 24th, 1885. Ex-Surgeon, P. & O. Service.

To the Editor of THE LANCET.

SIR,—A glance at Section 488:4 of the Medical Digest will show that carbolic oil (*vide* THE LANCET, p. 546) has long been a remedy against these annoying insects; and in the same section several other valuable hints are given. I am, Sir, yours obediently,

Boundary-road, N.W., March 21st, 1885. R. NEALE, M.D.Lond.

To the Editor of THE LANCET.

SIR,—May I add another suggestion to that of Dr. Hovell? A teaspoonful (or less) of paraffin oil or petroleum well shaken up with, say, a quart of water, and applied to the face, arms, and exposed parts, will prove a useful protective against mosquitoes, &c. It irritates some skins if used frequently. I am, Sir, yours truly,

Leeds, March 23rd, 1885. FRANCIS EDWARD CANE.

L.S.A.—The whole question of titles is in a somewhat vague state as regards the law. The use of the title of "Dr." is not warranted by the qualification L.S.A. "Surgeon-Accoucheur" is also unfitted to the qualification. But it is not likely to call forth any prosecution.

Cymro.—Dunglison's (Churchills). A smaller work is published by Kimpton, Holborn.

INSTRUMENT FOR REMOVING FALSE MEMBRANE.

To the Editor of THE LANCET.

SIR,—Perhaps you will kindly allow me to state that the instrument for removing false membrane after tracheotomy, described in your journal last week, was made for me, according to my directions, by Messrs. Ferguson and Co., 40 and 41, West Smithfield, E.C.

I am, Sir, yours faithfully,

Bernard-street, W.C., March 23rd, 1885. BERTRAND SHADWELL.

A FREAK OF NATURE.

MR. WILLIAM LAWLESS, H.B.M.'s Consul for Martinique, Guadeloupe, and its dependencies, has favoured us with a letter from Dr. Massias, describing a monstrosity which recently came under his notice. The post-mortem examination of the creature, which only lived ten minutes, demonstrated the existence of two brains, two cerebella, two hearts, two stomachs, two livers, four lungs, two bladders, two spleens, &c. The genital organs, also duplicated and well developed, were male. The urethral canals and the rectums were not obliterated. A great peculiarity of this being consisted in the presence of four ears, two of which were situated in, and attached to, the occipital suture. The features were regular, and the mouth, nose, and eyes normal. The parents presented no abnormality of conformation.

Student.—An unqualified assistant has no right to use the title of "Assistant-Surgeon." It is everybody's business to prosecute such a person—and therefore nobody's.

House Surgeon is not entitled to a fee if the patient died in the hospital.

AN UNUSUAL MISHAP IN THE TREATMENT OF CYSTIC GOITRE.

To the Editor of THE LANCET.

SIR,—During the treatment of a case of cystic goitre in this neighbourhood, an event occurred which has never happened to me before. It is an accident which may seriously hamper the successful issue of any case, and therefore I would report it.

The goitre was of moderate size, situated principally on the right side of the neck, but some portion of the swelling stretched across to the other side. On tapping the cyst, the interior proved to be composed, as was previously expected, for the most part of trabecular structure; but there certainly was not more than one cyst, for the cannula, after it had been passed in, could be freely moved to the limits of the enlargement. Rather more than three weeks after the cyst had been continuously discharging through the cannula, and had been evidently day by day becoming smaller, the diminution in its size ceased, although the discharge still passed freely. Now it was reported by the patient that some days the discharge almost entirely ceased, then suddenly commenced again, and was for some time very copious; that on those days on which the discharge lessened the swelling increased, and when the discharge reappeared the neck as quickly diminished to its former size. On particularly examining the patient's neck, I noticed that the cannula was on the opposite side of the trachea to that on which I had inserted it. Its passage across from the right to the left side had been so gradual that until I had a special reason for examining the patient's neck I had not noticed this change of position. After further examination it was evident that the greater bulk of the goitre was on the right side of the windpipe, and that its cyst cavity emptied itself by a channel which must pass across the trachea into the much smaller cavity which was on the left side, and into which the cannula passed. That this was so was distinctly proved by pressing with the fingers on the swelling which was on the right side, for immediately there was an increased flow through the cannula and a decrease in the size of the swelling. I had injected the cyst with tincture of perchloride of iron (℥ii ad ℥i). It is, I am sure from experience, immaterial whether the liquor or the tincture is used for the purpose of converting the cyst of a goitre into an abscess.

It may be remembered that an anonymous writer in your journal of Dec. 2nd, 1882, wrote as follows: "It may be useful to point out that the writer of the article on goitre in Dr. Quain's Dictionary of Medicine makes the same mistake in recommending the tincture." This writer, whom you so kindly stood sponsor for when he was in doubt whether he should put his real name or the pseudonym "Chirurgus" to his letter, sadly betrayed your journalistic trust in him by misleading your readers and the readers of the article on Goitre in Quain's Dictionary, by asserting positively that it was a gross mistake on the part of the writer of that article to recommend the use of tincture of iron as an injection in cases of cystic goitre instead of the liquor. I trust by this time, for it is now more than two years since "Chirurgus" wrote his letter, that he has found out the mistake he has made.

I am, Sir, yours faithfully,

Canterbury, March 18th, 1885. PUGIN THORNTON.

THE etters of *Mr. Weatherly* (Oxford), *M.B.Lond.*, and many other communications, are unavoidably held over till next week.

"CONSTANT TINCTURES."

To the Editor of THE LANCET.

SIR,—If the numerous alkaloids found in opium, for example (of which morphia, codeia, narceine, and narcotine are the principal), were relatively constant, then the addition of "crude drug or spirit" would be admissible for "standardising." As they are not so, I cannot see how the process which Messrs. Squire say they adopt can "standardise" the amount of these alkaloids; of course, this could be done, but not with the "crude drug." I have nothing more to say upon the matter, further than that I am surprised, and at the same time glad, to know that these tinctures, which are prepared with the *crême de la crême* of drugs, "are very little dearer than the common tinctures (only a few pence in the pound)."

I am, Sir, yours obediently,

Park-terrace, Regent's-park, March 23rd, 1885. E. WHITE, L.S.A.

MEDICAL ETHICS.

OUR opinion has been asked of the conduct of a member of a Medico Ethical Society in writing applications for the post of medical officer to clubs and provident societies held by other medical men. Our judgment is that the procedure is a very unusual one, and one that cannot be commended.

RESECTION OF THE KNEE-JOINT.

To the Editor of THE LANCET.

SIR,—The "Mirror of Hospital Practice" in your columns is of the greatest value, especially as a guide to what may be expected in the aftercourse of an operation. It should also be a guide to outsiders in private practice in methods of treatment. I am therefore surprised to see a careful account of an operation at St. Mary's Hospital, in your issue of March 14th, where resection was resorted to for the knee-joint of a girl only ten years of age. The account states that the child's limb was ankylosed firmly and in a useless position, and that after the operation the limb was two inches and a half shorter than the sound limb. We are also carefully told that the epiphysis of the femur was "almost entirely" removed, together with a slice of the head of the tibia. Now, we may suppose the child to be at present of average height for her age. If so, I leave it to you to judge how many inches off the ground the faulty limb will be when she has done growing. The result of the ankylosis will be atrophy of all the muscles. We are told, "there was wasting of the muscles of the limb," and what use such a limb will be to her as an adult I am at a loss to imagine. The foot will probably grow, and the patient will have a leg the length of that of a girl of ten (or, allowing for growth at the opposite ends of the femur and tibia, of about thirteen), with the foot of an adult. But, apart from such prognosis, what I should like to know is this: Are such operations to be held up as examples to general practitioners and those in charge of cottage hospitals?—I am, Sir, yours faithfully,

March 23rd, 1885. A. OGIER WARD.

*** Our correspondent will observe respecting the case about which he writes, that it was a question of restoring to usefulness a limb, the knee of which was ankylosed almost at a right angle and still presented signs of disease. Under the circumstances, we hold that the operation which was performed was the one best calculated to obtain such a result, by straightening the limb and at the same time removing lurking mischief. The whole of the epiphysis of neither bone was removed, so that growth can still go on at the line of junction with the diaphysis both above and below the line of section. The muscles of the limb were wasted, as a consequence of prolonged disease, and, as in other cases, will regain to a considerable extent their power. The shortening, two inches and a half, partly the result of atrophy of the bones, but chiefly the result of operation, will be found of very little inconvenience to the patient in the future, and was unavoidable. If our correspondent will turn to Holmes's System of Surgery, vol. iii., p. 764, he will find a case recorded where, in spite of seven inches' shortening after excision of the knee-joint, the patient was able to walk, with the aid of a high boot, thirty miles in the day.—ED. L.

Inquirer.—The qualifications L.R.C.P.E. and L.R.C.P.Lond. do not justify the use of the title "Dr." Whether a board of guardians can be "compelled" to be exact in its use of titles is another question. The gentleman whose title is so misstated should himself make the correction.

Messrs. Funk and Wagnalls.—We cannot extend our exchange list.

A MONSTROSITY.

To the Editor of THE LANCET.

SIR,—Two days ago, whilst driving out, my attention was directed to a notice posted outside a tent somewhat to the following effect:—"A boy with four arms and four legs, but one head." I immediately alighted to see this freak of nature, and this was briefly what I saw. A native lad twelve years old, bright and intelligent-looking, chewing betel, slim, but not wasted. From his abdominal parietes in front protruded a pendulous growth. There was no sulcus between it and the point of union to what I should describe as its carrier. On the left (relatively to the carrier), a shoulder presented, and from it two arms. A little lower down came the nates directed forwards with the anus. Turning the growth forwards there was a penis uncommonly like a piece of shrivelled parchment. The proprietor of the nondescript growth objected to my separating the nates, as the proceeding hurt him. The owner of this rare appendage said that both he and it micturated, but that he alone defecated. The boy would not consent to his genitals being examined. The entire mass was freely movable, and of the same temperature (normal) as the individual, and no bony connexion between the two could be made out.

As this case is unique, quite different from the Siamese Twins or the Double-headed Nightingale, I have thought it worth recording. As the abnormality purposes exhibiting in London, you will have an opportunity of testing more fully what I merely saw very cursorily.

I am, Sir, yours faithfully,

H. KIERNANDER.

Bombay, March 6th, 1885. Surgeon, P. & O. Service.

Mr. C. Harrington.—The examination in surgery of the Apothecaries' Society is held the week before that in medicine, and must be passed by those wishing to obtain the degree of Licentiate, unless the candidate can produce evidence of having passed an equivalent examination elsewhere, such as the Membership of the Royal College of Surgeons.

"SWEET SPIRITS OF NITRE."

To the Editor of THE LANCET.

SIR,—From a paragraph in THE LANCET of March 7th it seems that the Council of the Pharmaceutical Society has informed the Inland Revenue Office that the medicinal value of sweet spirit of nitre does not depend on the nitrite of ethyl it contains, and therefore the presence of a definite amount of this constituent is not essential to the purity of the drug. If this be the case the Council has, it seems to me, committed an error; it has given an opinion on a therapeutic subject, and this opinion is not in accordance with the medical knowledge of the present time. The compilers of the British Pharmacopœia indicated their views of the importance of nitrite of ethyl by introducing a purity test which shows, though imperfectly, the quantity of the constituent present in spirit of nitrous ether. The most recent investigations tend to show that the compilers of the Pharmacopœia were right in the view they took. Dr. Hay in 1883 proved that nitrite of ethyl is a powerful medicinal agent, and in the same year I showed that spiritus ætheris nitrosi has precisely the physiological influence which might be expected from the nitrite of ethyl it contains. Undoubtedly, spirit of nitrous ether contains other ingredients, such as aldehyde, paraldehyde, nitrate of ethyl, &c., but the value of spirit of nitrous ether can in no way be connected with the presence of small quantities of these materials.

It may be true that the public often, and medical men sometimes, prefer a spirit made after older formulæ and containing less nitrite of ethyl, because the flavour of such a spirit is more agreeable than that of the pharmacopœial preparation. It is absurd, however, to accept this as evidence that nitrite of ethyl is not an essential constituent in spirit of nitrous ether.

It may be contended that spiritus ætheris nitrosi and sweet spirit of nitre are not the same drugs and should not be tested in the same manner; but, as a fact, no distinction is drawn between them commercially. When a medical man orders a patient to take sweet spirit of nitre he means the spiritus ætheris nitrosi of the British Pharmacopœia, and when the public buy the drug for themselves they believe that they are obtaining the preparation ordered by medical men. If sweet spirit of nitre, which contains only a trace of nitrite of ethyl, is allowed to be genuine by the Board of Inland Revenue, it will come to pass that in future the medical profession will not be able to count on the efficacy of the spirit of nitrous ether which they order.

I am, Sir, yours truly,

Owens College, March 23rd, 1885. D. J. LEECH.

UNUSUAL CAUSE OF CONSTIPATION.

To the Editor of THE LANCET.

SIR,—Although rare in this country, such cases as the one described by Dr. A. H. Watkins are by no means infrequent in Australia and other fig-growing countries, where the fruit may be obtained cheaply. In England I was, on one occasion, called upon to treat a man, aged seventy-two, for diarrhœa, which had been preceded by constipation. He complained of much pain, and a sense of constant weight at the lower bowel, and frequent, but difficult, micturition. I explored the rectum, from which a large hard mass of fig-seeds, &c., was removed by the handle of a spoon and injections of warm water. The means of weighing it were not available, had I desired such accuracy, but the accumulation *in situ* could have weighed little short of a pound. The diarrhœa ceased without further treatment, but the rectum did not regain its usual power for several days. This case, and, doubtless, those recorded by British authors, arose from the free use of *preserved* figs, but I can discover no reason why the freshly gathered, *fully matured* fruit should not tend equally to the formation of such troublesome accretions, where the usual laxative effect is not produced.

I am, Sir, yours obediently,

March 24th, 1885. J. G. BRIDE.

CURIOUS HEREDITARY MALFORMATION OF THE FOOT.

To the Editor of THE LANCET.

SIR,—The following are cases showing an extraordinary tendency to hereditary malformation of the foot; and as I think an account of them will prove of interest to your readers, I send you a brief one.

William S——, labourer, aged seventy-seven, has six toes on the left foot; his son George S——, aged fifty, his grandchild, Jane B——, aged nine, and his two great-grandchildren, Henry and Edwin S——, aged respectively two years and six weeks, have each of them six toes on the left foot. It is not unusual to find a supernumerary toe, and it is rarely that operative interference is required in such cases; but in the case of the two children the father wished the toes removed so that their boots might fit better. I removed the toe of the child Edwin on the 15th inst., by amputation through the metatarso-phalangeal articulation, and found there was a perfect joint. The left foot was slightly broader than the right, and the toes were perfectly formed. It is curious that in all these cases the supernumerary toe has been on the left foot. All are now living near here.

I am, Sir, yours faithfully,

Bridgwater Infirmary, Somerset, March 23rd, 1885. CLIFTON STURT.

L.R.C.P. Lond.—It is a good principle not readily to believe a report concerning a brother medical man which is to his discredit. We should recommend our correspondent to call on the gentleman he names and ask exactly what he said, giving him meantime every credit for having acted honourably. If he really said what is attributed to him, our correspondent would be justified in asking that it should be either retracted or justified. It would certainly be very difficult to justify such language in regard to such treatment, and that after our correspondent's responsibility had ceased for a week.

Dr. G. B. Ferguson (Cheltenham).—The paper will appear very shortly.

"HOW TO CARRY, UNAIDED, AN INSENSIBLE MAN."

To the Editor of THE LANCET.

SIR,—In reply to your correspondent "R. N. R.," I beg to suggest the following method:—Turn the individual upon his face, with the arms extended in a line with the body. Raise the trunk until he be in a kneeling position. Place yourself under him, so that his stomach rests on your right shoulder. Pass your right arm between the thighs and behind his right thigh. With your left arm draw his left hand forwards under your left, and grasp the wrist with your right hand: then raise yourself to an erect position. If you can obtain assistance in this operation, so much the better; or if there be a bed or table upon which the subject may be placed, he will be the more easily raised, or, rather, you will more easily raise yourself and burden. By this method the weight falls directly on your shoulders. The person carried cannot slip forwards, as you have his hand grasped from behind; nor can he slip backwards or off the shoulder, as your arm is over the thigh. The left arm is disengaged. Or, by reversing the operation, he may be carried on the left shoulder, in which case the left arm is passed behind his left thigh and his right hand grasped from behind. Your right arm is then free. This is very advantageous; as, for example, going down a ladder from an upper storey of a burning building where the rescued one is overcome by smoke, or where the operator wishes to carry weapons, &c., off the field of battle. The situation of the subject as above described may not be devoid of its inconveniences; but that need not be considered in replying to "R. N. R.," nor in certain other cases, as apoplexy.

Here is another method which I have seen employed:—Seat the subject with the legs flexed on the thighs, and these flexed on the trunk; the head will then rest on the knees. Pass a broad continuous strap (a soldier's belt, for example) behind the thighs at the popliteal spaces and under his arms. Crouch down behind him, *dos à dos*, pass the strap over your forehead, and raise yourself. The strap should be short enough to allow the weight to fall upon the shoulders and upper part of your back while you are bent slightly forwards. The head may drop backwards; but, if so, it falls on the top of yours. The strap, being under his arms, prevents him from falling through. Both your arms are comparatively free. By means of this strap I have seen Indians carry 300 pounds in weight (a barrel of pork) farther than one probably would care to believe. I am, Sir, very respectfully yours,

March 23rd, 1885. BEAVER.

"HYDROCHLORATE OF COCAINE."

To the Editor of THE LANCET.

SIR,—Your correspondent, Mr. Symes, must have misunderstood my letter, which appeared in THE LANCET of March 14th. I merely suggested a tried remedy for cocaine solution when it became flocculent. Mr. Symes' statement refers more particularly to a preventive of flocculi; and he calls attention to Dr. Fenwick's suggestion in his letter which appeared in your issue of Jan. 31st—viz., the use of camphor-water. I have again read Dr. Fenwick's letter, to which Mr. Symes refers, but I fail to discover any mention of camphor-water or any other solvent for cocaine whatever. I therefore conclude Mr. Symes must either have read Dr. Fenwick's letter very imperfectly, or have not read it at all. I am, Sir, yours faithfully,

Sussex Eye Hospital, Brighton, March 28th, 1885. J. CHURCHYARD.

"ON SYNCOPE, AND A METHOD OF AVERTING IT."

To the Editor of THE LANCET.

SIR,—I very gladly acknowledge Mr. Benham's priority in pointing out the efficacy of applying heat to the head in cases of syncope. At the time of writing on the subject, I was not aware that the value of this method had been recognised by anyone. The fact is, I am almost completely cut off from the opportunity of consulting books of reference on medical subjects by the discourtesy of the Birmingham Medical Institute, a society which acts on the principle of hiding under a bushel whatever light it may have the good fortune to possess.

I am, Sir, yours obediently,

Birmingham, March 23rd, 1885. WILLIAM J. NOTLEY, M.D.

THE EXPLOSION AT SHOEBURYNESS.

To the Editor of THE LANCET.

SIR,—I notice in THE LANCET of March 21st an account of those fatally wounded at the Shoeburyness explosion. In that account you leave out the name of Capt. Goold-Adams, who ought to have been included to make the list correct. My father was one of those wounded, and perhaps that is the reason I take particular notice of the mistake.

I am, Sir, yours truly,

CHAS. W. LOW, L.R.C.P. Lond., &c.

Powis Lodge, Vicarage-park, Plumstead, March 23rd, 1885.

B.A.—To reproduce in our columns the announcements would be to play into the hands of the advertisers, and would, we fear, not have the effect desired by our correspondent.

Competitor.—Our correspondent should write to the secretary of the Society, who will give him the information he requires.

INSOMNIA A CAUSE OF CONSTIPATION.

To the Editor of THE LANCET.

SIR,—I have recently had under observation the case of a young man suffering from slight eczema and pruritus ani, in which insomnia appears to have been a cause of constipation. The occurrence of constipation as a feature of atonic states of the neuro-muscular system is, of course, well known to the profession; but it is at first sight a little surprising to find that it may be brought on by a sleepless night. This, however, was repeatedly the case with the young man above alluded to, and the explanation doubtless is that insomnia intensifies the neurasthenia, and with it the lack of tone in the intestinal and abdominal muscles. In this instance the constipation disappeared, without the exhibition of purgatives, on the removal of the causes which prevented sleep. As constipation is frequently answerable for irritation and ulceration in the neighbourhood of the anus, it would probably be advisable always to inquire into the state of the nervous system when such a combination of symptoms presents itself. I am, Sir, yours faithfully,

F. R. WALTERS, M.D., F.R.C.S.

Moorgate-street, E.C., March 14th, 1885.

Mr. S. O. Eades, L.R.C.P. & S. Ed.—We learn, upon inquiry, that the Schedule has been in the meantime withdrawn.

"APPLICATION OF MIDWIFERY FORCEPS."

To the Editor of THE LANCET.

SIR,—Before me are a pair of forceps invented, or introduced to the profession, by Professor Hamilton of Edinburgh. They are, I think, what Mr. James MacMunn recommends in THE LANCET of March 7th. I used them for twenty-five years, until I retired from midwifery practice, and liked them well, although forceps blades had much improved in form and lightness in the interval. I would not have cared to trouble you with this note, did I not wish to ask whether young surgeons are using forceps too frequently, and whether they have found in forceps cases that recovery is less satisfactory than might be looked for in ordinary tedious cases? As a rule, patience is not without its reward in obstetrical practice. I am, Sir, yours truly,

Newcastle-on-Tyne, March 9th, 1885. J. CARRICK MURRAY, M.D.

Lambeth—The sum is not worth a legal process of recovery; and we think our correspondent was wrong in advancing it after specific instructions not to do so.

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Dr. Bristowe, London; Dr. S. Monckton, Maidstone; Surgeon-General Stewart, Lymington; Mr. Thomas Annandale, Edinburgh; Mr. Jas. Hall, Peel; Mr. J. G. Bride; Surgeon-Major Sargent, Bedford; Mr. A. E. Tanner, Tottenham; Mr. Churchyard, Brighton; Mr. T. Bond, London; Dr. Ferguson, Cheltenham; Mr. F. A. Lees; Dr. R. E. Dudgeon; Mr. H. Cartwright, London; Mr. F. W. Lowndes, Liverpool; Mr. Keay, Blairgowrie; Mr. C. Jones, London; Mr. T. W. V. CASE XI.

FIBROID PHTHISIS

ORIGINATING IN DRY PLEURISY

Lumleian Lectures

ON

SOME POINTS IN THE NATURAL HISTORY OF PRIMITIVE DRY PLEURISIES.

Delivered before the Royal College of Physicians,

BY SIR ANDREW CLARK, BART., M.D.,
FELLOW OF THE COLLEGE.

LECTURE II.

MR. PRESIDENT AND GENTLEMEN,—A careful study of the cases related with more or less completeness in my first lecture leads naturally and necessarily to the second stage of this inquiry. A full understanding of the clinical demands a solution of the pathological problem; they are inseparably connected, and find their common origin in dynamic disturbances, which, although sometimes intangible, invisible, and incalculable, constitute the ultimate nature or essence of disease. What, then, is the nature of the visible pathological changes originating, underlying, maintaining, and continuing the symptoms and signs characteristic of the course and issues of the cases set forth as the grounds of this inquiry?

But before describing those changes as I have observed them in the course of my examinations, I must clear the way to the better understanding of them by some remarks on the minute anatomy of the lung, and on the structural characters of a blood-clot formed in freshly drawn blood.

Setting aside the earlier and in sundry ways admirable accounts of the minute anatomy of the lung given by Addison, Rainey, Rindfleisch, Schultze, Charcot, Luppey Lefort, and Waters, and confining our examination to the accounts more recently published by such observers as Schäfer and Klein, we shall learn from them the views received and adopted at the present time. Here is what Schäfer says:[1] "After a certain stage of subdivision, each bronchial tube reduced to a small size is termed a lobular or respiratory bronchial tube, and its walls become beset with small hemispherical saccules termed air-cells or alveoli. They occur at first only here and there, and confined to one side of the tube only, but at length almost cover it, so that the tube in a great measure loses its cylindrical character. At length it ends in an enlarged completely sacculated passage, termed the alveolar passage, from which are given off blind ramifications, somewhat enlarged towards their extremities, and everywhere closely beset with the air cells. These enlarged terminations are named infundibula." In order to give as exact an expression as possible of these views, he illustrates them by a diagram given at page 516 of the work already cited. From Klein's Atlas and from his more recent masterly little Handbook of Histology I extract the following account, which on the whole is the simplest, clearest, and most accurate of any hitherto published concerning the minute anatomy of the pulmonary parenchyma: "The small or intra-lobular bronchi are cylindrical tubes; they divide dichotomously into smaller tubes, and ultimately pass into the alveolar ducts, which take up on all sides of their circumference the lateral alveoli; the ultimate parts of the alveolar ducts are the infundibula, which take up the terminal alveoli. The alveoli are spherical or polyhedral in shape; and those belonging to the same alveolar duct or infundibulum are separated by much less tissue than the alveoli of adjacent lobules." In the Handbook (p. 220), it is further said that "all ducts or infundibula are closely beset in their whole extent with spherical, or being pressed against one another with polygonal, vesicles—the air cells or alveoli—opening by a wide aperture into the alveolar duct or infundibulum, but not communicating with each other. The infundibula are much wider than the terminal bronchioles, and also wider than the alveoli."

To Rainey and to both these distinguished observers is due the merit of having cleared away much of the confusion in which this intricate subject was until recently buried, of having discarded a complex, misleading, and useless terminology, and of having made it possible for persons not investigators or experts to form a tolerably accurate and clear conception of the anatomy of the pulmonary parenchyma and of its relations to the larger air passages. But even yet the reform is incomplete. It is not enough to have swept away as mere subjective expressions such terms as primitive and secondary lobules, lobulettes, air sacs, and the like. Others supported by great authority remain; and, whilst either having no correlative facts, or conveying inaccurate representations of those really existing, they suffice to keep obscure that which is simple, and to render barren or fertile only in error the application of anatomical facts to pathological processes and practical work.

Schäfer, for example, speaks of bronchia, bronchioles, or respiratory bronchial tubes, of their endings in enlarged completely sacculated alveolar passages, and of the giving off from them of blind ramifications or infundibula enlarged towards their extremities and everywhere closely beset with air cells. Elsewhere he says: "At the end of the respiratory bronchioles, near the passage of the infundibula, all the cells which line the wall of the tube are of the non-ciliated pavement variety. But the air cells themselves, both those which are scattered over the respiratory bronchioles and those which cover the infundibula, as well as intermediate portions of the infundibula, which occur here and there between the air cells, possess an epithelium of a peculiar character."

Now, in this quotation, even with the help of the context, it seems to me impossible to find a clear, connected, and exact account of the terminal air passages and of their relations to the pulmonary alveoli. And this impossibility, as I view it, lies less in any error committed by this distinguished anatomist than it does in the multiplication of distinctions, forgetfulness of the archetypal idea of a respiratory organ and the use of terms which are at once confusing and useless. There are two necessary—and, as it happens, they are the only unerring—guides to the complete and accurate understanding of the structure of an adult organ. The first is the study of its comparative history throughout the animal series; and the second is the study, from beginning to end, of the course of its own development. Investigated after this manner, the difficulties encountered in understanding the minute anatomy of the lung disappear; and the relation of the air passages to the alveoli become so clear and easy of apprehension and expression, that the use of many and complex terms is neither necessary nor justifiable. The primitive type of a lung is a cylindrical tube, the sides and end of which are portioned out by delicate membranous septa into shallow cubical spaces, not communicating with each other, but only with the common lumen of the tube round which they are arranged. If one will imagine a corridor with open cubicles fully occupying not only each side, but the further end, the floor, and the roof; if one will also imagine that no free space is left between the cubicles, that they fully occupy the sides, roof, floor, and end of the corridor, that they do not communicate with each other, except through the corridor around which they are arranged; that the corridor imagined is surrounded without loss of space on every side by corridors and cubicles similarly arranged; that all these corridors lead outwards to the exterior of the house of which they form a part; that, as all these corridors run outwards, they are joined by others without enlarging through the junction; and that at first the corridors are so short as to have only a single or double row of cubicles, whilst further outwards they have three, four, or even more,—if you will imagine all these things, you will be able to frame a sufficiently clear and accurate conception of the simple way in which the pulmonary alveoli are connected with the pulmonary air passages, and these with one another.

To describe the relation of the air passages to the alveoli in a more formal and literal manner, we may take a lobule as the subject of description. Each lobule, more or less conoidal in shape, surrounded by areolar tissue with all its usual contents, and penetrated at its smaller end by the lobular bronchus and by bloodvessels, lymphatics, and nerves, constitutes, as we know, a miniature lung. As soon as the terminal bronchus enters the lobules, it divides and subdivides with increasing rapidity and but small diminution of size, until the dividing or branching process is brought to an end at the circumference of the lobule. At its entrance into the lobule the lobular bronchus is but scantily alveolated, and its direction is moderately straight;

[1] Quain's Anatomy, vol. ii., p. 514.

but in the second and third divisions, which diminish in size, the walls are alveolated throughout, and the direction is constantly changing. In the terminal portions of the air tubes or passages which do not diminish in size the division is extremely rapid, and the end of each passage is formed by its abrupt closure just beyond a final division. It is this fact which, when a section of lung, including the pleura, is examined from the deep surface, has led to the notion that the terminal passages or tubes form dilatations or sacs at their blind extremities. Fortunately, sections and dissections parallel to the long axis of a passage demonstrate this notion to be incorrect. If this view of the relation of the air passages to the alveoli be accurate, and long study of the subject makes me somewhat confident about it, there is no need for a complex and copious terminology. It will be enough to speak of the lobular bronchus, of the intra-lobular bronchi or bronchioles, of the inter-alveolar passages and of the alveoli.

The alveoli are almost always spoken of as being hemispherical or vesicular; and their relation to the air passages is often illustrated by reference to a racemose gland or to a bunch of grapes. Both the description and the illustration are alike erroneous and misleading. It is true that under forced inflation, and as a result of injection and of other manipulations, the alveoli do exhibit occasionally a distantly hemispherical shape. But this is abnormal. Lying on the walls of the terminal passages, varying a good deal in size and somewhat in shape, but fairly uniform in depth, they can best be described in the main as irregular cubical spaces. A single layer of a honeycomb rolled into a cylindrical tube and closed at one end by another single layer, the cells of both looking inwards, would illustrate better than anything else that I can remember the relation of the alveoli to the inter-alveolar passages. By carefully inflating and drying a portion of lung, and examining sections of it made at varying angles to the pleura under an inch objective attached to a binocular microscope, the statements now advanced with respect to the relation of the alveoli to the inter-alveolar passages may be easily corrected or confirmed by any competent observer. These remarks on certain points in the minute anatomy of the lung have led me from the main subject of inquiry further than I intended or desired. I excuse myself on the ground that an accurate and adequate knowledge of this subject is essential to a just understanding not only of pathological processes, but also of those respiratory sounds which we employ in the diagnosis of disease.

If a little freshly drawn blood is dropped upon a glass slide, permitted to clot, decolourised by gentle washing, and submitted to microscopic examination, three things and their mode of combination will arrest the attention of the observer: a basis substance arranged by wrinklings or foldings into varying sized areolæ, a faint and close network made up of minute molecular-looking fibres, and a small number of leucocytes. The fine fibrillar network will be seen to occupy the spaces enclosed by the areolæ of the basis substance. The leucocytes imprisoned in the basis substance, or in the fine fibrillar network, and undergoing some granular change, appear to be shooting out in all directions protoplasmic processes, and to be engaged in textural development. Examining such a specimen without any knowledge of its nature, it could be easily mistaken for a delicate glioma, and would be unhesitatingly received as a conclusive example of the development of fibrous tissue from leucocytes. But a further critical study of such a specimen will make it certain that no such development is taking place; that both the areolar basis substance and the fibrillar network are formed directly from the liquor sanguinis; that the leucocytes and their processes are in the way of degeneration; and that, whilst they and the fibrillar network will melt into a granular débris, the basis substance will remain unchanged.

I have related this experiment to show how easily one may be deceived by appearances when they run along the line of one's ideas, and how much care is needed in interpreting the changes which occur in recently exuded lymph. In this matter three structural elements are to be found: a fibroid basis substance, fibres, and cells. The latter are either migrated leucocytes or proliferating connective-tissue corpuscles; and it is held that from one or other, or both, the fibroid substance and the fibres are developed, and that the idea of the direct formation from an exudation of any sort of fibroid tissue must be definitively abandoned. In respect of the fibres formed in some kinds of lymph this contention is doubtless correct; but in respect of the fibres formed in at least one kind of lymph about to be mentioned no conclusive evidence has been adduced. In those exudations which consist of a fibroid basis substance and imperfectly formed white fibrous tissue, this theory cannot justly be maintained.

It is true that there are present in them leucocytes, and sometimes a few fusiform cells; but it is equally true that they do not exist in such numbers, nor show such changes of transition into fibroid materials as would warrant the inference of an exclusively causal relation between them. In such instances, as in the instance of the blood-clot, one may fairly hold that the fibroid elements have been directly formed out of the exudation, and that the cells present therein have taken at least no structural share in their development.

Leaving these collateral considerations, I proceed now to consider the chief forms of exudation produced in the course of primitive dry pleurisies. These exudations may be classed under three heads: the fibrinous, the croupous, and the proliferative.

The fibrinous exudation is characterised by the scarcity of its cell forms and its permanency; the croupous by the abundance of its cell forms and their rapid degeneration; and the proliferative by the abundance of its cell forms and the rapidity and variety of their structural developments. In no case does any one of these forms constitute the entire exudation; but in every case one variety predominates and determines the characters and the course of the changes which ensue. In its early stage the fibrinous exudation consists of membranes more or less extended and more or less thick, which can be detached from the pleura without apparent injury to its epithelial surface. This membrane is greyish, sometimes semi-transparent and elastic, but friable. It does not often adhere to the costal pleura, and it is more frequently found over the upper than over the under part of the lungs; indeed, its most frequent seat is around the summit of this organ. It is composed of a basis substance studded with moleculo-granular matter, shaped into rude areolæ or differentiated into bands of imperfectly formed fibrous tissue, and it contains embedded in it a few epithelial cells, some oat-shaped nuclei, and here and there a nucleated fusiform cell. Sometimes the exudation presents the appearance of an irregularly honeycombed or reticulated membrane, in the meshes of which there is found a yellowish, glutinous fluid, clotting on exposure to the air. In this fluid are found amorphous flakes, leucocytes, and red blood-discs. The structural constitution resembles that of the smooth membranous exudation; but it cannot be so easily removed from the pleura, and whereas the subpleural areolar tissue is in this instance congested, swollen, and infiltrated with a fluid containing many leucocytes, it is in the former instance apparently little if at all affected. At a later stage of its existence this fibrinous exudation becomes denser, harder, tougher, extends into the pleural matrix, and now, opaque and yellowish, cannot be detached without injury from the pleural surface. The subjacent pulmonary alveoli are for the most part little affected, but here and there their walls are thickened without apparent proliferation, and their cavities contain a fibroid substance, with epithelial cells and leucocytes embedded therein. At a later stage, however, when the fibrinous exudation invades the lung, further changes take place. This invasion, when it takes place, moves in the first instance along the lines of the interlobular fissures, and only at a later period steals along the bloodvessels into the alveoli. In well-marked cases, three striking naked-eye changes slowly appear in the wake of this invasion. The interlobular areolar tissue at the affected part is converted into thickened and indurated bands, which, in some instances, contracting and compressing the lobules, give rise to the appearance, rather rare, of a true pulmonary cirrhosis. In the second place, portions more or less extended of the pulmonary parenchyma become solid, hard, tough, dark, and creak under the knife, which cuts them with difficulty. And in the third place, along the course of the fibroid invasion, adjoining the consolidations, and at various parts of the summit and free margins of the lung, there are tracts or patches of vesicular emphysema. In the summit of a lung in which limited tubercular growths have undergone fibroid substitution, all these changes, the thickened pleura, the fibrous bands, the small consolidations and the emphysematous patches, will be found side by side. In addition to these changes, others less obvious will be found upon close examination. One of them is thickening of the adventitia and intima of the pulmonary arteries, and

the growth from the intima of minute fibroid nodules, which sometimes fill the cavity of the vessel. Another change is thickening of the alveolar walls, with the development therein of free nuclei, not apparently engaged in tissue development. A third change is the appearance in the fibrous bands, chiefly at their intersections, of small fibrous nodules, which resemble and are considered to be true grey granulations or tubercles. But neither the structural characters of the nodules nor the history of the patients in whom they are found justifies this interpretation. They are composed of a fibroid basis substance, having embedded in it numbers, never large, of small free ovoidal nuclei, a few nuclear fibres, and rarely a little elastic tissue. Each consists of one mass, and not of several masses; it does not, as far as I know, contain giant cells; and it never undergoes the cheesy change. Akin to these little nodules, there are sometimes found in cases of long standing, where there have been repeated exudations, larger lumps or flattened masses of like characters connecting the visceral with the parietal pleura, and looking like growths, from which it is not always easy to distinguish them.

The pleura, once the subject of fibrinous exudation, is liable to fresh attacks of inflammation, and to the formation of new membranes, superimposed upon the old. These new layers, although resembling each other in structure, are never completely fused into one, and on section can be easily distinguished. Between the layers there are left spaces, of various sizes, filled with a glutinous fluid, containing epithelial cells, leucocytes, and a few fusiform nuclei. These spaces are coated with an interrupted epithelium, and distantly resemble lymphatic sacs. This is the form eventually assumed by the reticulated fibrinous exudation when it is permanent. When only a single thin layer of this fibrinous exudation exists, vessels are not found in it. Even when there are several layers, vascularisation, as compared with the proliferative exudation, is exceedingly scanty; and it seems probable that the development of new vessels takes place rather by channelling and differentiation than by development through the medium of protoplastic cells. Lastly, this form of exudation is characterised by the scantiness of its cell constituents, by the slowness of the changes occurring in it, by its persistence, by its freedom from complication with caseous consolidations and bronchial dilatations, by the lines which it follows in invading the lung, by the rarity of its disintegration thereon, and by the insignificance of its effects upon the general health.

The croupous, or, as it was originally named by me, the corpuscular exudation occurring in primitive dry pleurisies, differs in many ways from the fibrinous on the one side and the proliferative on the other. It occurs for the most part at the middle and lower parts of the lung; it is yellow, soft, thready, unplastic, and full of fluid, containing multitudes of degenerating cells, hyaline globules, blood-discs, amorphous flakes, fragments of granular fibres, granular débris, and countless micrococci. Sometimes, without the occurrence of pneumothorax, these accumulations escape by means of minute openings in the pleura, through the lung, and the patient recovers. A single exudation, examined more closely may be divided into three parts. The first is an opaque, yellowish, and friable membrane of varying thickness, incapable of detachment from the subjacent pleura, with which it is apparently organically incorporated. The second is a loose, open, soft, areolated pseudo-texture, infiltrated with fluid. The third, occupying the free surface of the exudation, consists of incohesive, soft, fringe-like processes, which often break on handling. There is seldom any strong adhesion between the costal and the pulmonary pleura. When the exudation is very abundant, and occupies a considerable space between the visceræ and parietal pleura, circumscribed portions of it are sometimes found broken down and occupied by a fluid resembling pus. For the most part this fluid is not pus—not a fluid holding in suspension spherical globules of uniform size, structure, and mode of response to reagents; but a fluid holding in suspension disintegrating leucocytes and epithelial cells, granule cells, and hyaline spheres, oat-shaped nuclei, and broken fusiform cells, fragments of fibres, and granular débris.

The lung adjacent to the inflamed pleura is always affected to varying depths and in different ways. All the alveoli are congested, and contain desquamated epithelium and leucocytes. A few, but in my experience always a few, groups of alveoli are found in a state of hepatisation. Larger and much more numerous groups of alveoli are in a state of caseous consolidation. In the subpleural areolar tissue, in the interlobular fissures, and occasionally at the entrance of the vessels into the apex of the lobule, small yellowish nodules are seen, and may be commonly traced to lymphatics, from the proliferation of which, or of their contents, the nodules appear to arise. They are composed of an adenoid reticulum and of areolæ of common fibrous tissue, in the meshes of which are found masses of lymph-corpuscles, free, rounded, or oval nuclei, nucleated fibres, and numerous multi-nucleated cells in a state of active endogenous proliferation. Resembling in some ways tubercular nodules, they are often declared to be tubercles.

A close examination of the outer surface of one of the earliest formed layers of exudation will sometimes bring to light the existence of two sorts of minute openings. The one are stomata, chalice-shaped cavities, with epithelial lips and linings leading into lymphatic spaces. The other are minute openings, the mouths of burrowing and sometimes branching tunnels, which occasionally can be followed into the pulmonary alveoli. It is not improbable that when a croupous exudation melts, it sometimes makes its way through these tunnels into the lung, and is thence discharged. In a case which I recently attended with Dr. Barnes and Mr. Merriman, a puerperal pleuritic croupous exudation led, by melting, to the formation of three small encysted empyemas. Paracentesis having been considered inexpedient, the pyoid collections were left to nature. After a week, in the neighbourhood of one of the sacs there was heard a coarse moist crepitation; a few days later the crepitation became a bubbling rhonchus; and shortly afterwards some ounces of a pyoid fluid, quite different from genuine pus, were expectorated. The same procession of events attended the emptying of each sac. Meanwhile there was no single sign of pneumothorax; and although the thoracic walls corresponding to the empyemas were bulged, there was no displacement of the heart or of other organs. The patient is now completely convalescent. Sometimes this pleuritic croupous exudation has a constitutional origin, and then the affection may be bilateral. With a low capacity for organisation, this exudadation exerts at times a considerable influence for evil on the subjacent lung. The effect consists sometimes in disseminated caseous or lymphoid consolidations, sometimes in fibroid changes, and sometimes, although rarely, in small excavations or in bronchial dilatations. Basic lung disease akin to that described by Mitchell Bruce and others now and then arises in this manner. The tissues of this exudation are, in at least one respect, remarkable. When the case pursues a favourable course, the exudation is for the most part entirely absorbed, and I have once or twice learned from examination after death, that within a few months of an attack, every vestige of its presence has been removed. Now and then the fluid part of the exudation is absorbed, and the residue, becoming dry, undergoes caseation. In this condition calcareous plates and particles are occasionally deposited in it, and the patient becomes subject to obscure and often recurring attacks of pain.

The proliferatve pleuritic exudations which I now proceed to describe are of more frequent occurrence than the other two, more varied in their course, and more enduring in their larger issues and effects. They are still further distinguished in their origin from fibrinous and croupous exudations; for whilst the latter are preceded by the phenomena of inflammation, and accompanied by an abundant fluid exudation, the former sometimes arise, increase, invade the lung, and undergo textural changes unaccompanied by any other phenomena except those belonging to a slow and simple textural growth. Indeed, this variety of proliferative exudation often passes almost imperceptibly into pleural new growths, and further on I shall have to advert to several cases of this kind. Beginning in the subpleural connective tissue, and accompanied from the first by active cell proliferation, this exudation passes through the pleural matrix in two ways. Accompanied, as is usually the case, with an abundant fluid plasma, the exudation reaches the pleural surface without apparent breach of continuity. Unaccompanied by any such fluid, proliferating cells arranged in pointed groups push their way through the pleural matrix, and, making breaches of continuity therein, reach the epithelial surface, spread rapidly thereon, and unite to form a continuous proliferating neo-membrane, which at various parts differs in aspect, consistence, and thickness. The even membranous form, however is not always maintained. Sometimes, when the masses of cells and fibres are

loosely disposed and soaking in a glutinous fluid, the free surface assumes the honeycombed or alveolated appearance already described in connexion with fibrinous lymph. Sometimes, when unaccompanied by any fluid, the free surface becomes studded with clusters of granulations, nodules, or sessile warty-looking lumps; sometimes it is clothed with papillæ, or with fringe-like branching processes. In either case adhesions are speedily contracted with the costal pleura, and the intervening space becomes slowly filled by the connecting bridles, bands, or masses of actively proliferating lymph. The meshes of the exudation become filled with fluid; and when the meshes are large and the fluid abundant, the movements of breathing heard when listening to the chest with a stethoscope beget plural râles which are difficult to localise and understand. After a time the whole space between the pleural layers becomes filled with a solid exudation, and this, increasing in density and in hardness, becomes, with the visceral and costal pleura, fused into a tough, unyielding fibrous reticulated and laminated mass.

The structure of this exudation varies with its age. In the beginning, or at least as soon as it can be examined, it consists of an obscurely fibroid, and sometimes areolated basis substance, of a close network of fine molecular-looking fibrils, of leucocytes, nucleated cells, fusiform fibre cells, and desquamated epithelium. In addition to these elements, there are always present in varying amount, oval or oat-shaped free nuclei, red discs, and a few hyaline spheres. After a short time the network of molecular fibrils entirely disappears, the basis substance remaining becomes more distinctly fibroid, and constitutes a fundamental support for other changes in progress; leucocytes, or round cells resembling them, increase; fibre development from cells advances; new vessels shoot out in various directions; active cell proliferation subsides, and the bundles of freshly formed fibrous tissue become arranged either in lamina, when they sometimes exhibit a striking resemblance to unstriped muscular tissue, or in areolæ, through which communication with lymphatic spaces or channels is ultimately established. But whilst development has been thus proceeding towards the costal pleura, it has been also, in a certain number of cases, advancing into the substance of the lung. In the first instance it is only the subpleural alveoli which are affected, and their first mode of affection is a croupous, or more rarely a caseous, consolidation. Later on the proliferating exudation steals along the interlobular fissures, consolidating the peripheral alveoli of the lobules, seizes upon the peribronchial and perivascular connective tissues, enters the lobules of their roots, and travels along the terminal air passages, bloodvessels, and lymphatics into the alveoli. During this time the proliferating exudation consists essentially of two parts, constantly varying in their quantitative relations to each other, of the proliferating and fibre-growing cells, and of the fibroid basis substance already described. Sometimes, without obvious reason, the one predominates, sometimes the other; but they always concur; and when the alveoli are affected the cellular part always predominates in their walls and the fibroid in their contents. In the course of this progression of the exudation from the superficial to the deep parts of the lung, and from the root or from the circumference to the centre of a lobule, all the pulmonary tissues become affected; and the kind and degree of the affection determine the aspects which the lung shall afterwards assume, and the course which the malady will eventually pursue.

It may be said in a general way that the first effect upon the pulmonary textures consists in vascularity and swelling, the second in hardening and contraction, and the third in caseation and destruction, or more often in destruction without caseation. According to my own observations, they may, in abstract, be described in the following manner. The interlobular areolar tissue, increased in vascularity, swells, proliferates, hardens, and develops occasionally in its midst, either small, tough, fibrous-looking knots, or minute lumps and lines of cheesy stuff. Increasing in breadth, the interlobular septa encroach upon the lobules and compress them in various directions, and, at the root of a lobule where the bronchus enters and the vessels enter and emerge, the parts become so constricted by the fibroid invasion that their nutritive and functional activities are seriously depressed, and the integrity of the lobule as an organ is put in growing peril. The smaller branches of the pulmonary artery are greatly thickened by proliferative swelling of the outer and inner coats, and the latter coming to look like a richly nucleated laminar fibroma, develops on its free surface granules or nodules, sometimes large enough to obstruct the lumen of the vessels. Some of the capillaries are obliterated, some are dilated, some are aneurysmal, but all are thickened, and in many the centres of their endothelial plates are occupied by larger or smaller groups of proliferating free nuclei embedded in a fibroid substance. The terminal bronchi in the midst of the indurating exudation are affected in divers ways. Sometimes they are thick, hard, and compressed; sometimes they are soft, loose, thin, and generally or locally dilated. There is, however, almost always thickening of the adventitia, with the occasional deposit of minute caseous lumps therein; the muscular coat is in a state of degeneration or undergoing fibroid substitution; the elastic bands are still undisturbed; and the mucous membrane, congested, infiltrated with a fibroid basis substance, and studded with oval and oat-shaped nuclei, has for the most part lost its ciliated epithelium, which is replaced by a layer or layers of columnar, cuboidal, or flattened cells. The alveolar walls are irregularly thickened, the intercapillary spaces are occupied by a nucleated fibroid tissue, which at one part destroys a portion of the capillary network, and at another projects into granulations or nodules; the alveolar endothelium is replaced by layers of subspheroidal or flattened cells; and the alveolar cavities, already encroached upon by the thickened walls, are at some points occupied by masses of a fibroid substance, with a few round or oval nuclear particles therein. From the concurrence and co-operation of these and other structural changes the affected portion of lung is at length brought into a condition which practically, if not theoretically, must be regarded as a pathological autonomy or entity. In this state the affected portion of lung encapsuled by layers, more or less numerous and thick, of indurated pleural lymph, diminished in size and irregular in form, heavy, dense, tough, and uncrepitant, feels like a mass of indiarubber of unequal thickness throughout. The surface of a section made through such a lung, intersected by fibrous bands, springing from and returning to the thickened pleura, and broken by the patulous mouths of bronchi and bloodvessels drawn closely together, is of a dark-reddish-slate colour, veined between the septa with whitish branching lines, studded with fibrous knots or caseous granules, and closely spotted with muco-purulent points. Cut with difficulty and creaking under the knife, the affected lung when compressed yields from the smaller bronchi larger or smaller quantities of inspissated pus, and, from the parts between, a sometimes scanty, sometimes abundant serum, rich in blood-discs, leucocytes, pus-globules, nucleated cells and fibres, hyaline and granule spheres and free nuclei. Under various names, and ever since pathological anatomy has been cultivated, this condition of lung has been a subject of discussion among pathologists. It is the grey induration of Andral and Addison, the pulmonary cirrhosis of Corrigan, the fibroid of Sutton, Bastian, Moxon, and Wilks, and the chronic interstitial pneumonia of Charcot, Wilson Fox, and Hamilton. Furthermore, this fibroid induration represents in part an early stage of the condition of lung eventually developed by the habitual inhalation of irritating particles of coal dust, stone, or steel.

For an indefinite time, and even beyond the average duration of life, this condition of lung may in favourable circumstances remain stationary, and be found compatible with fair health and all the ordinary duties and enjoyments of life.

But circumstances are not always favourable. In failure from any cause of the general health, and especially under the influence of recurring irritations of the respiratory passages, the various changes constituting the fibroid lung advance, and out of them by metaplastic or by other methods new ones arise. For a time the new and advancing changes are still compatible with tolerable health. But sooner or later they assume a regressive character; the tide of action turns against the organism, and by slow degrees it succumbs. Examined at this stage, the lung exhibits, in addition to the alterations already described, sundry new ones. These are minute accumulations of fat, patches of vesicular emphysema, excavations of various forms and sizes, and, in an uncertain but not large number of cases,[2] cheesy masses and bronchial dilatations. To some of these alterations I shall

[2] I exclude from this statement minute alveolar caseations, almost always present in the immediate neighbourhood of lymphatic pleural exudations

devote a few remarks. Unquestionably some of the emphysemas present in the fibroid lung are the results of physical forces acting in well-defined conditions. But a certain number arise in a different manner, and for the most part they are to be found in the midst or on the borders of the fibroid indurations. It is probable that these emphysemas are produced by more or less complete obstructions of minute branches of the pulmonary artery. For in certain experiments which I performed some years ago I found that by injecting sand or finely powdered glass into the jugular vein, and so producing embolism of some of the intralobular branches of the pulmonary artery, fatty usure, and then emphysema, followed in the territory supplied by the blocked vessel.

Of the excavations or dilatations met with together or separately in the degenerating fibroid lung three deserve notice: the fibroid, the caseous, and the bronchiectatic. The simple or fibroid excavations are small, elongated, irregular, and contain a thin, and sometimes blood-stained, pus. When comparatively recent the surface of the cavity is soft, shaggy, and congested; it is composed of mere fibroid stuff in a state of dissolution, and of fragments of the elastic areolæ of the alveoli, seen by the help of a simple lens, hang from it like bits of tangled thread. When of ancient date, the interior of the cavity is smooth, vascular, and apparently formed by an organised membrane; it is, however, nothing more than an infiltration and induration of the lung substance immediately surrounding the cavity; and although the cavity in some sense secretes, its enlargement proceeds by disintegration of the free surface and a less proportionate "filling in" from behind. The contents of this form of cavity, never a true pus, is produced in some degree by metaplastic processes, but in the main by degenerative and necrotic changes. Unless when old and stationary, elastic areolæ and the débris of disintegrated bloodvessels are always to be found in the contents. The caseous excavations are small or large; the small excavations appear to be formed by a process of necrotic dissolution pure and simple. In the interlobular fissures they seldom extend, and almost always heal through secondary fibroid processes. The large caseous excavations are also, in the main, produced by the chemical changes which finally determine necrotic dissolution; but in a small degree proliferative and metaplastic processes concur, and hence the presence in such cavities of pus-globules, free nuclei, and nuclear fibre.

The caseous masses sometimes found in the interior of the fibroid lung vary much in size; sometimes about the size of a garden pea, they are occasionally larger than a walnut. They are composed principally of epithelioid cells, and in small part of leucocytes, of free nucleated bodies, and of much granular débris, pervaded occasionally by an obscurely fibrillated basis substance. They arise plainly enough in proliferation of the alveolar epithelium, and in the secondary textural changes which that proliferation after a time originates. Sometimes, when small, the masses are surrounded by fibroid tissue. The cause of their development is difficult to determine; but as far as my own personal observations go, the conditions of their genesis are brought about by the concurrence of gradual thickening or compression of a branch of the pulmonary artery, with obstruction, more or less complete, of the neighbouring lymph channels.

Concerning the bronchial dilatations and bronchiectatic cavities, it must be observed that, in the first place, contrary to what might be expected, in a greatly contracted lung they are present only in a small minority of cases. The dilatations are of three kinds: cylindrical, fusiform, and globular. No single hypothesis of their mode of origin hitherto advanced seems adequate to account satisfactorily for the whole facts accompanying their development. Sometimes they are present when there is little induration or contraction of lung; and sometimes when induration and contraction are extreme they are absent. To traction of the thoracic walls and of the interbronchial fibroid tissue as factors in the evolution must be added the active forces in certain conditions of inspiration and expiration and degenerative changes in the bronchial walls. In every dilated bronchus such changes are to be found, and they consist, for the most part, in fatty degeneration of the cartilages, necrotic coagulation of the muscular tissue, and fibroid invasion of the parts below the basement membrane of the mucosa.

Cavities in connexion with dilated bronchi arise at least in two ways: from necrotic solution of caseous lumps in the peribronchial areolar tissue or peribronchial alveoli, and from ulcerations of the bronchial mucosa penetrating the alveoli. When formed, these cavities become, of course, subject to the same dilating forces of the bronchi; and not only under the influence of the general respiratory forces, but also under the traction of neighbouring cicatricial bands, they assume the most varied and irregular forms.

Thus altered by the further invasion of the fibroid process and by its secondary effects, the lung with its consolidations and cavities, its fibrous nodules and caseous lumps, presents the characters of ordinary phthisical disease, and would be commonly regarded as a variety of the tubercular process. And if it be true that the nature of a disease is to be determined not by its completed history during life, but by the structural changes discovered after death, then it must be confessed that there is much to be said in support of the popular view of the tubercular unity of phthisical disease. And if, still further, we accept without reserve the experiments of Koch and the assertions of his followers, that in every such lung as I have just described certain bacilli will be found, and that the terms "tubercular" and "bacillary" are co-extensive and convertible, then it must be conceded that the debate is closed and the question settled.

But for my part, supported as these statements are by the most ingeniously devised and carefully executed experiments, I cannot accept them in the subject under consideration, with unconditional reserve. For in several cases of phthisical disease following upon fibroid invasion of the lung, I have failed to find the tubercular bacilli in the expectoration or in the lungs. To this it has been replied, that if the investigation had been properly conducted, the bacilli would certainly have been found. The only answer that I can make to such an assertion is this: that the process which fails to reveal veritable bacilli in fibroid perfectly succeeds in tubercular cases. But assuming, for the sake of argument, that tubercular bacilli are to be found in every ulcerative non-malignant disease of the lung, and that, unlike every other organ in the body, it is insusceptible of any other chronic inflammatory or ulcerative process but the tubercular, our difficulties are not at an end. It is not easy to see how mere differences of constitution and soil can reconcile, with the exclusive action of a single causal agent, the widely differing histories of the affections now grouped under a single species by the bacillary hypothesis. And the difficulty is not entirely met by the reply of "chronicity," when we remember how, into whatever texture or organ we pursue it, the structure of the tubercle in acute tuberculosis is always the same. It is quite true that in the lung a tubercle when it appears excites fibroid and pneumonic changes, and that one or the other, or both, may so increase as to completely hide the tubercular nodule; it is quite true that sometimes the fibroid, and sometimes the pneumonic change, predominates; and that, in the latter case, the progress of the pathological changes is speedy, and that in the former it is slow; it is quite true that in the tubercular nodule there is a fibrous element, and that sometimes its growth is so disproportionate to the other structural elements that it extinguishes them; and it is quite conceivable, although in over four thousand autopsies I have never seen such an occurrence, that in a veritable tubercular lung one could nowhere find, in its fibroid consolidations, conclusive evidence of the former existence of the tubercular neoplasm. All this is true, or conceivably true, but it does not refute the observations made by others as well as by me, that inflammatory and non-inflammatory fibroid products may invade, alter, and disintegrate the lung without the presence at any time of either the true tubercular nodule or of the veritable bacillus. To assert that a fibroid pulmonary induration is incapable of ulcerative excavation except through the medium of tubercular bacilli is, to say the least, an unproved assumption; and, for the present at least, has no greater claims to unconditional acceptance than the assertion, made with equal confidence a year or two ago, that the presence of giant cells in a given growth was conclusive as to its tubercular nature.

Finally, it must not be forgotten that in accepting the bacillary hypothesis as a dogma no longer to be questioned, we shall have to range under one name diseases which, with apparently nothing in common but the presence of bacilli, are yet not only in the same body but even in the same organ, widely different in their symptomatic characters, course, duration, effects, and issues; and that, unless we are to lose some of the most precious parts of our recently acquired knowledge, and to ignore distinctions justly

founded on concurrent clinical and pathological observations, we shall have to re-classify bacillary affections in such a manner that, whilst the bacillary supremacy remains acknowledged, the differentia giving them permanent and real, although subordinate, individualities shall be formulated and maintained.

The homoplastic are not, however, the only changes which occur in the exudations of primitive dry pleurisies. Metaplastic changes arise; and out of the simple structural elements of the proliferative exudation are developed such changes of form and of arrangement as constitute, within certain limits and conditions, fibrous, syphilitic, leprous, and other growths. But neither upon them nor upon the larger considerations which they suggest have I time at present to dwell. Reviewing the pathological changes brought about by primitive dry pleurisy, it becomes plain that they may be properly arranged as so many pathological entities in four divisions: the neoplastic pleuritic membranes, the fibroid lung, the bronchiectatic lung, and the fibroid phthisical lung. The complete and adequate understanding of these pathological changes is undoubtedly important, but it is not sufficient; for, although sometimes they are the direct results of injury coming from without, they are in the majority of instances the anatomical renderings or structural expressions of underlying states of system which are of the essence of the disease, and demand the first and chief attention. To these dynamic states we should now naturally turn in order to learn how, by their integrations and disintegrations, their ceaseless groupings and shifting equilibria, they originate, maintain, transfigure, and end the varying structural forms which are the only visible manifestations of their presence. Such an inquiry, however, would lead us into the realms of speculative pathology, and leave out of sight the clinical uses of our anatomical study. To this humbler task let me proceed; and in trying to show that the pathological entities have corresponding clinical autonomies, let me endeavour to turn the knowledge of this relationship into use for the daily business of our lives.

Before proceeding with this task it may be useful to state more formally than I have done the position which, at present, the bacillary hypothesis seems to held in the scientific mind. In the first place, it is held that there is nothing autogenetically distinctive in the structure or form of a tubercle; that what alone makes a growth tubercular is the presence in it of the tubercular bacillus; that tubercular bacilli are present in all tubercular and scrofulous products which are thus in nature essentially identical; and that their absence, at some given time from such growths, is not a proof that the bacilli have never been present, but merely that they have been destroyed by some curative change in the tissues invaded by the parasites. In the second place, it is held that the inoculation of certain healthy animals with the tubercular bacilli is followed invariably by an eruption of acute general tuberculosis, and that the tubercles thus begotten, as well as their successors for generations, remain inoculable and virulent. In the third place, it is held that the inoculation of healthy animals with substances not containing tubercular bacilli are invariably infructive, or fructive only in products which are either sterile or beget only local effects. In the last place, it is held that the true and sole causal agent of tubercular, scrofulous, and allied diseases is the tubercular bacillus; and that the various forms which they assume, and the different courses which they follow under the irritative action of the bacilli, are accidental results due to local peculiarities of structure, the influence of external circumstances, and the constitutional tendencies of the invaded organism.

But whilst some of these contentions are proved, and some are probable, they are neither universally nor unconditionally accepted. There is a minority of persons, and I place myself among them, who contend that the exclusively causal agency of the bacillus, although extremely plausible, is not conclusively proved; that a greater number and variety of experiments of control are yet needed to satisfy a just scepticism; and that, even now, in the affections discussed, there must be admitted the existence of bacillary and of non-bacillary consolidations; and therefore of a bacillary and non-bacillary phthisis.[3]

At the present time, when men are still in the fervour of their conversion to the brilliant experimental discoveries of Koch, such protestations of a sober judgment will be regarded as unpardonable sins, and punished with suitable severity. Well, the sufferers under chastisement must console themselves with the reflection that it is only those whose judgments have been disturbed by emotion, or who have never sounded the deepest depths of knowledge, or who have not passed through the perils of its subtlest casuistries, that are exempt from difficulties, or doubts, or fears; and that for the most part truth is won, not by those who rush impetuously forward in its pursuit, but by those who, with open and eager mind, are yet in patience content to "labour and to wait."

[3] De La Phthisie Bacillaire, par le Professeur G. Sée, 1884.

Croonian Lectures

ON THE

HYGIENIC AND CLIMATIC TREATMENT OF CHRONIC PULMONARY PHTHISIS.

Delivered at the Royal College of Physicians,

BY HERMANN WEBER, M.D.,
PHYSICIAN TO THE GERMAN HOSPITAL.

LECTURE II.

Curative Treatment. — Relation of Doctor and Patient. — 1. Diet: Defective Digestion; Raulin's Researches on Mineral Substances; Milk; Times of Meals; Cures of Phthisis; Alcohol. — 2. Air and Ventilation; Open-air Treatment; Defective Arrangements for the Treatment of Phthisis in General Hospitals; Brompton and Ventnor Hospitals; Necessity for numerous Small Hospitals for Phthisis in the Country. — 3. Exercise. — 4. Management of the Skin; Clothing.

MR. PRESIDENT AND GENTLEMEN, — With regard to the curative treatment of phthisis, the main points which we ought to aim at are: improvement of the general nutrition of the body, or, to use Dr. Beale's expression, of the "bioplasm"; restoration of healthy respiration and circulation in the lungs; limitation of the existing disease; prevention of fresh outbreaks or fresh infection. The principal means to obtain these ends are: adequate supply of food; abundance of pure air by night and day; regulated exercise; strengthening of the skin; healthful occupation of the mind. We might perhaps say, in other words, that we must aim at improvement of the tissue change by increased supply of pure air and nutritive material to the cells and tissues, and by perfecting the elimination of used-up material; but we must, at the same time, keep off impure air from the diseased spots. I shall discuss the hygienic treatment under the following heads:—1. Food. 2. Air and ventilation. 3. Exercise and rest. 4. Bathing and management of the skin. 5. Climate.

Allow me, however, Sir, before I enter into these points to say a few words on the relation of the doctor to the consumptive patient. Shall the doctor frankly tell the latter that his disease is phthisis? It is still the opinion of many eminent medical men that we should, as a rule, not do so. As long as phthisis was considered an incurable disease, there may have been reason for such concealment, but now, as we know, and can tell our patients, that phthisis is a curable disease, I think the patient ought to be informed of his condition, more or less according to the individuality; and as far as my experience goes this has a salutary effect. The patient is more ready to co-operate with the doctor, and to bring the great and long-continued sacrifices, for he becomes aware of his own large share of responsibility. I have already alluded to the circumstance that intelligence on the part of the patient and his friends is a great help towards recovery in phthisis, and that want of judgment or insight into the nature of the illness, and of the manifold dangers, and into the means of cure, renders the prognosis less hopeful, unless we are able to place the patient under the strictest superintendence of a judicious doctor, or, still better, in a health establishment under the control of a resident medical man and his assistants, or into a well-arranged special hospital.

1. *Diet.*—All those who have been successful in the treatment of phthisis have paid much attention to the question of food. Sir Risdon Bennett and many other physicians have shown that by "feeding" alone great service can be done. If the popular idea were correct, that the appetite and digestion of consumptive patients are specially good, it would be more easy to cure phthisis; but the rule is rather the reverse. The poorer the blood and nutrition of the cells and tissues, the greater therefore the want—the less is often their desire for food. The appetite is not rarely capricious, and the digestion is apt to be disturbed. It happens also that patients object to the diet ordered, and it is therefore sometimes necessary to tell them plainly that without their cordial and constant assistance in this matter they have no chance of recovery. At the same time, however, the fancies of the patient ought not to be disregarded. The food which he desires, if it is in any way permissible, ought to be procured for him. It ought to be as varied as possible, and the cooking and serving of meals ought to be nice. The example of others is mostly very useful; and this is one point in favour of special establishments and health-resorts for phthisis, as at Goerbersdorf, under Dr. Brehmer and at Falkenstein under Dr. Dettweiter. I have also seen at Davos and St. Moritz patients in company with other patients eat and drink, with regard to quantity and quality, what they would never eat in their own rooms alone, or with members of their families. Though it is impossible to lay down fixed rules for all cases, one rule is almost general—namely, that those suffering from consumption ought to take the amount of food required by frequent small meals, and not by only two large meals, as in French, or three meals, as in German and Swiss hotels. This is one of the reasons why ordinary hotels are in general not adapted to the treatment of active phthisis. In addition to breakfast, lunch, and dinner, there ought to be four supplementary meals—namely, early in the morning, between breakfast and lunch, between lunch and dinner, and at bedtime. Before passing in review some of the principal articles of food, I wish to direct attention to the possibility that there may be important relations between the life of the tubercle bacillus and the quality of the food that we take, especially the saline materials which enter into the composition of the blood, the cells, and tissues. A short time ago I had the pleasure of listening to a suggestive lecture delivered by Dr. Vivian Poore at the Society of Arts, in which he related the results of most instructive researches by M. Raulin on the growth of the Aspergillus niger. A short account of these researches is given in Dr. Duclaux's "Handbook on Fermentation," prepared for the International Health Exhibition in 1884. After much trouble, Raulin found the following liquid the best nutritive medium of the aspergillus. It is known as Raulin's liquid:—Water, 1500 grammes; sugar candy, 70 grammes; tartaric acid, 4 grammes; nitrate of ammonia, 4 grammes; phosphate of ammonia, 0·6 gramme; carbonate potassium, 0·6 gramme; carbonate magnesia, 0·4 gramme; sulphate of ammonia, 0·25 gramme; sulphate of zinc, 0·07 gramme; sulphate of iron, 0·07 gramme; silicate of potassium, 0·07 gramme. By sowing the spores on this fluid, two crops of aspergillus can be grown, which weigh together 25 grammes; but if we prepare the fluid without the potassium, the gathering will dwindle to 1 gramme only; the crop has, therefore, fallen to $\frac{1}{25}$th of what it was. It will fall to $\frac{1}{2000}$th if the phosphoric acid, and to $\frac{1}{1000}$th if the ammonia, be withdrawn. The withdrawal of the zinc would reduce the crop to $\frac{1}{10}$th of what it was in the complete liquid—in other words, would bring it down from 25 grammes to $2\frac{1}{2}$th grammes. Duclaux points out that the zinc—in weight only $\frac{1}{3000000}$th of the fluid—increases the crop of the plant by 700 times its own weight; and he further states that, if $\frac{1}{1000000}$th of nitrate of silver be added to the nutritive fluid, the vegetation stops abruptly. We learn from this that microbes require mineral food in the same way as plants and animals do, and if we knew exactly which mineral substances the tubercle bacillus requires, and could, without harm to ourselves, deprive our blood and cells and tissues of these salts, by abstaining from food containing them we should deprive the bacillus of the means of existence. The investigation of these matters, however, is very difficult. It is not easy to construct the best nutritive fluid for each microbe. It can only be obtained by a series of methodical researches. When the best artificial medium has been created, it must be first ascertained that the result of the sowing of the spores is always uniform, otherwise the result of the withdrawing of certain elements cannot be calculated. It is further evident that a study of agents impeding or destroying the growth may also become very important. With regard to the different articles of food, Dr. Bidder, of Berlin, points out from several papers by Dr. Bunge, of Dorpat, that the food of carnivorous animals contains a larger quantity of soda and smaller of potash than that of herbivorous animals, and he reminds us that carnivorous animals are on the whole less subject to tuberculosis than herbivorous animals. If it could be proved that the potash salts are more conducive to the growth of tubercle bacillus than soda salts, articles of food containing excessive properties of potash ought to be taken only sparingly.

Milk is regarded by the majority of medical men as one of the best articles of food in the treatment of phthisis. It contains all that is required by the body, and the mineral matters in the best proportion. It is less irritating than other nourishing kinds of food, and is more easily digested. There are differences in the quality of the milk of different animals, and also of the same animal, according to the food consumed by it, and other influences; but when merely speaking of milk we mean cow's milk. The dangerous substances which can be introduced by it, as the fever poisons and the tubercle bacillus from cows affected by the disease, and principally those with diseased udders, are, so far as we know, destroyed by boiling. We ought therefore, unless we are perfectly sure about the milk-supply, always to recommend the milk to be boiled. Patients often say that milk disagrees with them, but I have only rarely been able to acknowledge this statement as correct. In some cases where there is a tendency to diarrhœa or sickness, or acidity of the stomach, it is necessary to dilute it with from one-third to one-sixth of lime-water, which often exercises a soothing influence on the mucous membrane of the intestinal canal, and may, besides, help to bring on the cretaceous change in caseous deposits. In other cases, especially where there is constipation, the addition of Apollinaris or natural Selters, or Bilin water, is useful; in others that of barley water; in others, a small quantity of coffee, tea, or cocoa renders the milk palatable to persons who have a dislike to the taste of pure milk. In many instances the addition of rum or cognac promotes the digestibility of the milk, especially in persons accustomed to stimulating food, including much alcohol, but this addition ought to be made only under the guidance of the doctor. The quantity of milk suitable to different invalids varies very much, indeed, in the same person at different periods of the disease, and also according to the amount and quality of other food consumed. I generally advise from one and a half to three pints in twenty-four hours, but in many cases, especially those complicated with albuminuria, I restrict, sometimes for weeks, almost entirely to milk and milk food.

I dare not discuss other articles of food in the same way as I have done with milk. Everyone interested in dietetics will find valuable information in the works of Playfair, Frankland, Pavy, and Bauer.

About diet in general I will confine myself to some general rules. 1. To induce the individual to take as much nourishing food as his digestion permits, and to endeavour to increase the appetite and digestive powers by air and exercise, and sometimes by medicinal substances. 2. To give as much choice and variety as can be obtained. 3. To avoid articles of food, or of relish, of inferior nourishing value, if by these the appetite for more necessary articles is diminished, or the digestion of the latter is disturbed. Such articles are, for instance, acids, salads, and especially uncooked acid fruits, sugar, and pastries, a list which might be largely increased. Potatoes ought to be taken only in very moderate quantities. They contain much potash in proportion to soda, and experience shows that the exclusive, or even preponderating, use of potatoes favours scrofula.

I have mentioned before that in the majority of ordinary cases of phthisis, except the very chronic and arrested forms, it is better to take the desirable amount of food in frequent small meals than in two or three large ones. I am in the habit of recommending a plan of the following kind, with many modifications according to circumstances:—At seven o'clock or earlier, while still in bed, a cup of milk by itself, or with a dessert- or tablespoonful of cognac, or with lime-water, or with a small quantity of tea or cocoa and a small piece of bread-and-butter. At half-past eight or nine, after dressing, breakfast of milk, with some slightly stimulating addition, as tea, coffee, or cocoa, bread-and-

butter, or bacon, ham, or fish. At eleven, a tumblerful of milk or koumiss, or sometimes a cup of broth or beef-tea, or a sandwich and a glass of wine. At one or half-past one, a substantial meal of meat, or poultry, or fish, or game, with fresh vegetables, some light pudding or cooked fruit, and a glass of wine. At four o'clock, a glass of milk or koumiss, or a cup of tea or coffee with much milk, and some bread-and-butter or plain biscuits. At seven another substantial meal similar to that in the middle of the day. At half-past nine or ten, on going to bed, a cup of milk, or bread-and-milk, or milk with some farinaceous food, as Hart's, Liebig's, Nestlé's, or Mellin's. At this time, if there are night sweats, the addition of a tablespoonful of brandy is very useful.

In cases of considerable pyrexia it would be injudicious and impossible to give as much solid food as in chronic non-febrile or nearly non-febrile cases, but it is necessary to give as much easily digestible food as the patient can digest. Our aim ought to be somewhat to check the waste, and to replace by food the increased waste. Here alcohol is of great use. Milk is often not digested in its natural state, but it must be tried peptonised and diluted with pure water, aerated water, or, still better, with barley-water or thin gruel. Chicken broth, veal broth, beef-tea, and gelatinous substances are in these conditions most useful; while in health, and in the non-febrile consumptive cases, they ought not to take the place of the more solid proteinaceous substances. In most cases of phthisis it is desirable to introduce into the system a fair amount of fat, and this can often be done better in the shape of bacon, fresh butter, and milk and suet, than in the form of cod-liver oil, though the latter, too, is most useful. There are some popular "cures" of phthisis into which milk or different kinds of fat, assisted by open air, enter largely. You all know the milk cure in the various mountain districts, from the time of the Romans to the present day; the koumiss cure in Tartary. I remember also the buttermilk cure in some German villages, and have often heard that in the American prairies consumptive patients are cured by consuming large quantities of the bone marrow of the buffalo. Many years ago, when assistant at a clinic at Bonn, two of my poor consumptive patients left me to be cured in a neighbouring village by taking three times a day or more frequently a large plateful of a kind of porridge prepared of dog's fat and rye meal, and certainly their improvement was most remarkable. But they had exchanged at the same time their in-door town work for out-door country work. All these cures have two points in common: first, food rich in fat and proteinaceous matter; and, secondly, out-door life.

I cannot close the chapter on food without entering into the debated question of alcohol. Much as I am convinced that in health alcohol is rarely necessary, in phthisis, especially in the febrile stages, experience has convinced me of its great usefulness in the majority of cases so long as the kidneys are sound. It acts as respiratory food (Binz) and limits the waste of tissue. Brehmer, Spengler, Unger, Rüdi, Volland, and Dettweiler use it largely; Austin Flint, too, is a strong advocate for its use. The quantity and quality required vary very much in different cases. In some cases as much as a bottle, and even three pints, of moderately strong wine, or ten to twelve ounces of cognac or whisky, are taken in twenty-four hours with advantage; in others scarcely one-sixth of this amount; and, again, in others alcohol must be altogether avoided. Alcoholic drinks seem to be specially useful in those cases where a pretty large quantity can be taken without unpleasant excitement or headache; but where, on the contrary, a sense of comfort and increased strength is produced by them, where appetite and digestion are improved, flatulence and indigestion removed, and pyrexia, where it exists, is diminished. Where, on the other hand, they cause throbbing in the arteries, headache, listlessness, flushing, or great excitement, or loss of appetite for ordinary food, they are either unsuitable or can only be taken in small quantities. The doctor must decide by careful examinations whether, and in what quantity, alcoholic drinks are to be given. The quality, too, cannot always be known without trial. In Germany and Austria the stronger Hungarian wines are much liked; in the Alps the red wines of the Valteline; but Madeira, Marsala sherry, Burgundy, good claret, and some pure Italian and Greek wines are likewise useful in many cases, and not rarely beer; cognac and whisky suitably diluted are of great value in cases of weakness. Very often Dr. Dettweiler's plan, to give the amount of alcohol required in very frequent and small doses, is of great practical value.

2. *Air and Ventilation.*—Although it is generally acknowledged that impure air is the foremost cause of phthisis, and although Dr. Henry Mac Cormac, Dr. B. W. Richardson, and others have preached not only this, but also that pure air is the most important means of cure, yet we must all confess that in practice the first principles of air treatment are, with rare exceptions, most imperfectly carried out. Wherever climate permits an entirely open air and tent life is the best help in the treatment of phthisis; but this is not easily practicable the whole year round in our climates, although much might be done in this direction. Fears of the inclemency of the weather are far too great amongst the public as well as the profession. Patients affected with chronic consumption, without or with only moderate and partial pyrexia, ought to spend the greater part of most days in the open air, and ought not to be deterred by a little rain, or mud, or low temperature, or by the fact that they begin to cough when they come out of the close house into the open air. Arrangements ought to be made by which invalids are enabled, warmly dressed, to sit in the open air, sheltered from wind and rain. It is here where the degree of intelligence of the patient forms an all-important element in the chances of success. It is necessary, as I have already stated, to give the patient and his friends an idea of the nature of the illness and the means of cure, and to obtain their intelligent, courageous, and persevering co-operation. The patient must see that though it is more difficult to carry out the open air principles in an inclement climate, that it is yet infinitely more injurious to him to shut himself up in close rooms than to use every possible moment of even an indifferent day to walk or sit in the open air. The improvement of the appetite, the digestion, and the strength, the diminution of night sweats, of restlessness, and mental depression, are in most instances so marked that the invalid after some time begins to have confidence, and to feel that his life is rendered more bearable even if no cure can be effected. We must always bear in mind that even in the midst of large towns the air in open places, and even in the streets, is very much purer than within the houses. The researches of Angus Smith, Pettenkofer, and others have shown this with regard to the proportion of oxygen and carbonic acid and other impurities; and those of Miguel with regard to the number of microbes in the air at Paris manifest this in a most striking manner. Their proportion within the wards of the Hôtel Dieu and of the Notre Dame de la Pitié being much larger than in the Rue Rivoli. As, however, the greater part of the twenty-four hours is spent in-doors the arrangements of the house and of the rooms are of the greatest importance. The invalid ought to have sunny rooms, sitting- as well as bed-room, for, though the sun does not shine at night, the vivifying influence which it exercises on the air of the bed-room during the day does not disappear at once with the cessation of the sunshine, but lasts through the night and longer; 2000 cubic feet per head is not too much space for each inmate, and by good ventilation the air ought to be frequently renewed by day and by night. The temperature ought, if possible, never to exceed 62° F.; and the open fire is by far the best producer of artificial warmth; gas ought to be entirely excluded. The bed ought to be open on all sides, and the ordinary consumptive invalid ought not to be longer than eight or nine hours in bed, even if the body temperature is somewhat raised during some hours of the day. It is a horrible custom to keep such invalids during the greater part of the day in bed unless the weakness be extreme. In all diseases it would be a useful subject of discussion when a patient is to be in bed and when not; when he is to take exercise and when to sit or lie still. But in phthisis the long stay in bed, and particularly in the bed-room, is certainly injurious; breathing, ventilation of the lungs, circulation, appetite, tissue change, almost everything is unfavourably influenced. In acute forms and stages of phthisis, when there is much fever, I do not advise the patient to take active exercise, or to fatigue himself by sitting up during any length of time; but it is certain that pure and fresh air is as necessary, and even more so, than during the non-febrile stages. The bed of the patient ought therefore to placed so that he receives as much open air as possible without exposure to actual wind or draught. In summer, and also in winter, weather permitting, a couch or bed ought to be placed on a balcony or terrace, or in an open field or garden; the patient ought to be carried to it and properly covered, lay there from morning to night, or as long as possible. Some

of my patients have spent during weeks, or even months, a great part of the day in hammocks slung up between trees, with great advantage. The change from the ordinary bed treatment in a close room to this open air couch or hammock treatment is an infinite gain to the patient who breathes more, eats better, is more cheerful, sleeps more soundly, and is less troubled with perspiration. The pyrexia, likewise, often rapidly decreases. I shrink at present from touching the open-air treatment of the poor at their homes, except so far as they likewise should be taught to be as much as possible in the open air, and to sleep with open windows; and I may add that I have seen many instances where a change to open-air occupation in all weathers, from indoor work in close workshops or bakehouses, has led to an arrest of disease and recovery. I must enter, however, a little more fully into the treatment of poor consumptive patients in our general hospitals situated in large towns. There they have usually only between 800 and 1200 cubic feet of air per head, with ventilation through open windows, which cannot be efficiently carried out without draught, and is in winter often sadly neglected. The majority of these patients, even if there is only moderate and partial pyrexia, spend the whole, or by far the greater, part of every day in bed, which, as I have already said, ought not to be, excepting in acute cases, or stages, or in excessive weakness; but if, after the subsidence of the pyrexia, they are out of bed standing, or sitting, or walking about in the wards, they are exposed to draughts, and frequently contract fresh attacks of bronchitis or pleurisy, or other illnesses due to chill, and thus take further steps in their downward course. Although I have always been fond of hospital work, these considerations have for a long time been a source of worry to me whenever I stood at the bedside of my consumptive patients, and in despair I have more than once said that they were in the worst place in the world; and yet the hospital to which I am attached stands on an open spot at Dalston, and has small plots of ground attached to it where convalescents can sit and walk, while the hospitals in the interior of London are mostly deprived of this advantage. This is, indeed, a subject, gentlemen, which deserves your serious thought, and I earnestly entreat you, if you agree with me, to enlighten the public and to use your influence to procure better accommodation for the treatment of the consumptive patients of the poorer classes. I know that many medical men, and perhaps some of those whom I have the honour of addressing, are not in favour of special hospitals. If the general hospitals are well arranged for the treatment of phthisis, and situated in good air, some of my objections fall to the ground, but these favourable conditions are rarely met with. Very much better are the arrangements in the Brompton Hospital for Consumption, especially in the new building, which I had the advantage of seeing quite recently with Dr. Theodore Williams. Each of the three floors devoted to in-patients consists of a corridor 10 ft. in width, a large central dining-room, ten wards 13½ ft. high, holding from one to eight beds—forty-six in all. The average floor space per bed is 115 ft., the cubic space being 1400 ft. The ventilation is maintained independently of the windows and fireplaces, and supplies 4000 cubic feet per hour to each patient. The air is admitted by numerous openings placed on a level with different floors—on the east and north into the galleries, on the west and south into the wards, the greater portion being heated by passing over coils of hot-water pipes; a part is admitted directly. The quantity of hot and cold air can be modified at will, and the temperature is capable of being evenly maintained. The foul air is drawn off from the corridors, wards, &c., through extracting flues built in the walls, and furnished with openings at floor and ceiling. These flues run into large air ducts beneath the roof, which communicate with four towers heated by steam coils, forming the exhausting chambers. With these arrangements it is possible for patients to walk about in the corridors, or to sit in the central hall and converse with one another without being exposed to draughts and chills. It was a great pleasure to see almost all the patients out of bed. The drawbacks unavoidable with the situation in London, especially with the east and north-east winds, are the ordinary contamination of the air and the occasional fogs, and the fair results obtained show how much good can be done by judicious treatment and arrangement in spite of such a grave natural defect.

Infinitely more advantageous is the situation of the National Hospital for Consumption at Ventnor, with which I have been acquainted for many years past, and which I have lately again visited, under the guidance of Drs. Coghill and Robertson. The Undercliff is so well known to you that I need not give a description of the delightful and healthy situation. The peculiarities of the arrangement are, you know, that the whole hospital is built in blocks for twelve patients each, that each patient has a separate sleeping room of from 1500 to 1750 cubic feet, and in the newest block 2000; that each six patients have a separate sitting-room, 3000 cubic feet space, and each block (twelve patients) has an additional room in which breakfast, tea, and supper are served, of 3000 cubic feet; that male and female patients dine separately in large rooms at the end of the blocks. There are various arrangements for the renewal of air, which, though they would be regarded as satisfactory in other hospitals, have not appeared so to the authorities of the institution, so that in the new block, on Dr. De Chaumont's recommendation, a supply of 5000 cubic feet of fresh air per head per hour has been adopted, and the fresh air is to be delivered at a temperature of 62° F. Dr. Hassall has rendered a great service to the public and the profession by originating the foundation of this hospital. Between the hospital and the sea there is a large piece of open ground for exercise and sitting in the open air. The diet of the patients is well arranged; the results of the treatment are satisfactory, and the patients are mostly very happy during their stay. What I should like to add are terraces and balconies, on which light beds or couches could be placed for febrile patients to lie on, and thus to enjoy the open air; and, further, large verandahs, glass covered, and with movable glass doors to be opened and closed at will, so that patients might sit and walk there during wet and windy weather. Further useful additions would be seats with shelter overhead and on three sides, turnable so that the shelter might be turned against the wind, and the patients sit there with the whole front open, even in rain and windy weather. I should also be inclined to erect in suitable places walls with reflecting surfaces, to serve as shelter from wind and as reflectors of the sun's warming rays. Hammocks would be at times likewise a comfort.

There are, also, small sanitaria for consumptive patients at Bournemouth and Torquay; but the number of beds added together is almost infinitesimal compared with the number of consumptive patients belonging to the poorer classes. If there were a hundred of such hospitals they would be a fair instalment of what is required to meet the most necessary wants. I should not recommend large hospitals, but small ones, for 80 or 100 beds, with from one to three or four patients in each room; with balconies to hold one bed, so that one febrile patient could be moved into the open air, and more than one such ought never to be in the room. There should be large verandahs for exercise and sitting in wet and windy weather, shady and sunny seats, seats such as roughly sketched above, with turnable shelter to be used in windy and wet weather; and in other respects arrangements similar to those at Ventnor and Brompton. Each hospital ought to have a resident medical officer, and there ought to be ample room for exercise on level as well as on rising ground; the neighbourhood of a pine forest would be a farther advantage. They ought to be in the country or at the seaside, on account of the greater purity of the air. Even in the suburbs the air is much purer than in the interior of towns; thus Miguel found in ten cubic inches of the air of Montsouri (a suburb of Paris) 7600 microbes; in the Rue Rivoli (in the centre of Paris) 55,000; and a still much larger number, as already stated, in the hospital wards, especially in the winter. It would not be difficult to find fairly suitable localities. Surrey, Kent, Berkshire, and Hampshire have good sites. On the southern slopes of their pine-clad hills—for instance, between Leith-hill and Ewhurst Windmill, between East Grinstead, Frant, Wadhurst, and Ticehurst; between Ripley and Cobham; on the Chobham ridges; between Farnborough, Minley, Bramshill Park and Eversley; near Haslemere, on the slopes of Black Down and Hind Head. The southern coast and also the south-eastern offer fair localities, if care is taken in the selection of the spot with regard to shelter, dryness of soil, and exercise ground. The Undercliff, for instance, and the neighbourhood of Bournemouth still possess some not yet overcrowded sites; also Torquay, Sidmouth, Lyme Regis, Dawlish, Hastings, and perhaps Sandgate; on the coast of North Devon and Cornwall and near Llandudno and in Bute good spots could be found. I know, gentlemen, that small hospitals for consumption such as I have suggested are expensive, and that it would be difficult to find the money, but if you are convinced of the advantage to the

patients, and will use your influence, donations and legacies will come in, and in the course of time we shall take a step in the right direction.

3. *Exercise.*—Exercise is one of the most powerful and essential means of cure. It is as necessary as air and food, because it enables the invalid to take both in a sufficient quantity to improve the nutrition by taking up fresh material and removing the waste, and thus to fight a battle with a fair chance of success. Without exercise I should not like to treat phthisis. To take exercise properly requires, however, the guiding hand of the physician; there are judicious persons who can be taught to become sufficiently acquainted with their entire condition and their surroundings to enable them to do neither too much nor too little, but such persons are rare amongst consumptive invalids. In many of them the nutrition of the brain has suffered as much as that of the stomach and lungs and other systems, and their judgment with regard to their own state and their wants is impaired. We ought, therefore, to bear in mind that by far the majority of those suffering from phthisis require constantly to be held by "leading reins," and must be told what kind of exercise to take, how much, and at what times; walking on level, climbing gently, and with measured increase as to duration and steepness. Riding on horseback, skating, and tobogganing are all useful exercises under guidance, but over-exertion ought to be carefully avoided, and one mistake often destroys the fruit of months and years of judicious management. Up to a certain point the sense of fatigue is a guide, but not always, for some persons feel fatigue at the beginning of a walk and improve while taking it, and others never acknowledge to themselves the sense of fatigue. The medical man alone can measure the amount of strength, and how it can be maintained and increased by gradually increasing exercise. Climbing is especially useful, as it brings the whole systems of circulation and respiration into play, and leads to expansion of the lungs and thorax and strengthening of the respiratory muscles. Regulated climbing for a course of weeks and months in suitable cases has a wonderful effect on every organ and function of the body; not only respiration and circulation, but the digestion, the action of the skin, sleep, mental power, resistance to changes of temperature, all show the beneficial effect, and we scarcely doubt that this is due to an improvement of Beale's bioplasm, or "living matter," in the cells. Riding on horseback is likewise excellent exercise, exhilarating and accelerating the circulation, and through this the respiration; and it has been the principal means of treatment in several cases of recovery under my observation (Sydenham). Riding on donkeys may, in some localities, be substituted for horse exercise. Tricycling is likewise useful to some invalids. Pulmonary gymnastics—i.e., a methodical deep inspiration, followed, after a pause, by full expiration, practised in pure air several times a day are very useful in chronic non-febrile cases. Well-arranged exercises of the upper extremities materially assist the expansion of the apices and the subclavicular regions. Where active exercise is impossible from great weakness, or forbidden from inflammatory complications, the movement in a Bath chair is especially to be recommended, and by turning the head against the wind it can be used in almost all weathers. Open carriage exercise is likewise good, but there ought to be very little wind, or some arrangement for sheltering from the wind, by having, for instance, the front hood up, and sitting with the back to the horses, which can be well arranged in landaus. Those who have the chance of being moved in a boat up and down a river, or on calm days on the sea, often derive great benefit from this mode of motion. In some cases under my observation well-arranged journeys, in agreeable company, in rowing-boats, or small yachts, or steamers up the Thames, the Rhine, the Main, the Neckar, the Danube, the Isar, the Seine, and Meuse, have had very beneficial effect on body as well as mind, and the latter ought never to be forgotten in phthisis. In some very chronic cases of nerve prostration, with inability to walk and to take food in sufficient quantity, massage can with advantage take the place of active exercise, being a powerful accelerator of tissue-change, and leading to increased breathing and improved circulation. I have as yet had only a few cases in which I have recommended a plan somewhat analogous to that of Weir Mitchell and Playfair, though very much less energetic, but with evident advantage on the nutrition, muscular and and mental energy. It appears to me, so far as my experience goes, that there should be no active lung symptoms. The open-air treatment has been combined in those cases with massage, the patients having been placed during a greater part of the day on couches in the balcony, or in the garden. Walking exercise was not allowed during the first part of the massage treatment, but was gradually substituted for it.

4. *Strengthening of the Skin.*—Weakness of the skin is one of the prominent features as well in the tendency to phthisis as also in the developed disease, and ought always to be taken into consideration and remedied if possible. A slight change of external temperature, or exposure to a slight draught or change of clothing is apt to produce chill, which by reflex action is thrown on the lungs; it is also a frequent source of bronchitis and catarrh of the lungs, and also of digestive derangements and a great obstacle to recovery in phthisis. Constant exposure to the open air and exercise are the best tonics for the skin, and often suffice by themselves; but in many cases these must be combined or preceded by the judicious use of hydro-therapeutics. The skin has never been altogether neglected in England either by medical men or the public, while on the Continent the neglect has been incredible, and is still so in many localities, hence systematic hydro-therapeutics have had their origin on the Continent; and in the treatment of phthisis too Brehmer was the first to introduce them with special modifications,—viz., powerful cold douches to the chest of very short duration. Unger, Spengler, Dettweiler and others have continued and modified this system; Jaccoud, Sée, and other French physicians are powerful advocates for hydro-therapeutics. Much benefit is no doubt obtained by well-adopted procedures, but they require most careful management by the medical man. Even the ordinary treatment of the skin in itself ought to be guided by the doctor, who will not only examine the state of the skin, but also the condition of the heart and circulation in all its bearings; the degree of reactive power must be cautiously appreciated and gradually raised. In great weakness dry rubbing by an attendant of one part of the body after another is all that can be done; then rubbing the chest with a moist towel, and dry rubbing afterwards. Later on a very rapid sponging with tepid, and again later with cold, water, followed by a short return to bed, and a light, warm breakfast. It requires a considerable degree of reactive force to bear with advantage on rising in the morning the sponging of the whole body by cool or cold water, followed by brisk friction as daily practised by the majority of us in health, and forcibly recommended by J. Henry Bennet, whose views on the hygiene of phthisis have exercised good influence. A rapid plunge into cold water is in many cases of fair reaction the best plan. In others a very short shower bath, and, again, in others a tepid bath for a couple of minutes, followed by a momentary cold shower or plunge into cold water. Many sound hints on bathing and on the management of the skin may be gathered from the editor of the "Book of Health," in his article on the skin. Although by this means the skin becomes strengthened, yet the invalid ought never to neglect woollen clothing from head to foot. He ought not to overload himself with heavy garments while walking or riding, but he ought to have plenty of warm wraps when he sits down or takes passive exercise. The influence of dress on health has been well discussed in a paper by Mr. F. Treves in the "Book of Health," and Pettenkofer's little book, translated into English by A. Hess, is full of useful information.

CASE OF ANEURYSM BY ANASTOMOSIS ON THE HEAD,

TREATED BY LIGATURE OF THE COMMON CAROTID ARTERY, AND SUBSEQUENT LOCAL LIGATION.

By G. B. FERGUSON, M.D., & G. A. CARDEW, M.R.C.S.,
SURGEONS TO THE CHELTENHAM HOSPITAL AND DISPENSARY.

ANNIE S——, aged nineteen, came first under the observation of Mr. Cardew at the Cheltenham Dispensary, in November, 1881. She then complained of a pulsating swelling at the back and right side of the head, involving also the right ear, which was greatly enlarged. She had had some swelling about that position throughout the whole of her life, the first stage having been a nævus, which had never been subjected to any treatment. During the twelve

months previous to her seeing Mr. Cardew the tumour had increased rapidly in size, and had frequently burst, severe hæmorrhage in each case ensuing. The patient was a strong-looking girl of short stature, who, with the exception of occasional headaches, had enjoyed excellent general health. On examination, a considerable tumour was visible, evidently a cirsoid aneurysm, otherwise styled aneurysm by anastomosis, extending from the back of the right ear to the occipital protuberance, and extending as high and descending as low as the upper and lower borders of the temporal bone, occupying, in fact, about twenty square inches. The tumour was of a pulpy consistence, and pulsated forcibly, as also did the ear. A loud thrill was audible over it. It was covered with small and thin-walled venous projections, which were the sites of the frequent hæmorrhages. After a specially severe and dangerous hæmorrhage about the middle of December, 1881—she was stated then to have lost about three pints,—her friends and herself became seriously alarmed, and requested the institution of some radical treatment. Accordingly she was shortly afterwards admitted into the Cheltenham Hospital, and came under the care of Dr. Ferguson. There, after due consultation, it was decided that the common carotid artery should be tied, and this was accordingly done in the ordinary manner and with the full Listerian precautions that have been employed by all the surgeons of the Cheltenham Hospital since the year 1876. The operation presented no difficulty, and calls for no remark save that, the omo-hyoid muscle passing apparently somewhat higher than is usually the case across the neck, it was easier to secure the artery below than above the muscle; in which former position it was accordingly reached and tied. The ligature was of chromic catgut of medium thickness, most obligingly sent to Dr. Ferguson by Sir Joseph Lister. And in order that his kindness should not be unnecessarily trespassed on hereafter, we would desire in this place to repeat Sir Joseph's information, that chromicised catgut of identical quality can be supplied by David Marr of Holborn. The patient's progress after the operation was typically satisfactory, there having been neither pain nor any (even the most trifling) elevation of temperature. In fact, the dressings were finally removed on the eleventh day after the operation, exposing then the firm cicatrix of a wound that had evidently healed by first intention. The immediate result of the operation was the shrinkage, almost to disappearance, of the tumour and the complete cessation of the pulsation. It was, therefore, no small disappointment to notice after the removal of the dressings that a slight pulsation was again perceptible over the site of the tumour. However, she was shortly afterwards dismissed from the hospital in good health and spirits and well pleased at the result of the operation. During the next six months her history presented no points of special interest, save that the tumour became still less noticeable, and that the pulsation remained obscure. But after this six months' period of quietude a collateral circulation succeeded in establishing itself to a somewhat considerable extent, and the tumour began again to increase and pulsate somewhat after its former fashion (though much less forcibly), and there was even some recurrence of hæmorrhage. This being the case, Mr. Cardew (to whose care she had returned) determined to ligature the tumour subcutaneously. One half of the tumour was accordingly ligatured with a silk thread in the usual manner, the latter being tightly tied. The result was the entire stoppage of the pulsation in the part tied. The silk was tightened every day for ten days, after which time, when it had almost cut its way out, it was removed. This process of ligation brought about a notable consolidation of one-half of the tumour, and this at the expense of but little pain or suppuration. Some few days afterwards the posterior auricular artery was ligatured on a pin, which had been first passed under it, this step being taken in consequence of its large size and evident connexion with much of the remaining pulsation. Two months later the other half of the tumour was similarly ligatured subcutaneously, and again, six weeks later, as an additional safeguard, the whole was once more subcutaneously re-ligatured. With this last ligation the treatment ended, almost complete obliteration of the tumour having been effected, with an entire removal of the hæmorrhagic tendency; and on inspection of the patient on March 7th, 1884, and eighteen months after the cessation of treatment, it was evident that a substantial cure had been effected. Some slight softness only was apparent at the position of the former growth, but there was no feeling of pulsation anywhere, save over an artery in the position of the occipital, and the ear, which was formerly so tumid, had returned to a moderate size. The hæmorrhagic tendency had not again manifested itself, and the patient's health and spirits were of the best.

Remarks.—The chief interest of this case lies in its close resemblance to the one treated by Mr. Storks and Sir William Fergusson, and narrated in the latter's System of Practical Surgery (p. 151), where much information respecting such cases will be found. Sir William Fergusson, however, trusted more to obliteration of the vessels in the growth by pins and ligatures, and Mr. Cardew to ligation *en masse*. In respect to all such cases it may be doubted if the treatment by pins or direct ligation could be safely applied without the preliminary tying of the chief nutrient artery, in reference to which question the following remarks of Sir William Fergusson are much to the point. "The practice above described was certainly attended with considerable hazard, both on account of the inflammation as well as the hæmorrhage, and it was not without misgivings that I adopted it. But the case seemed otherwise hopeless, and the previous obliteration of the common carotid led me to trust that such bleeding as might occur could be controlled. Without this preceding step it may be doubted if the result would have been equally successful; and I am therefore disposed to attribute the satisfactory issue to a combination of the two methods—viz., first, the obliteration of the main arterial current towards the disease, and then the destruction of the vessels in its substance." It is interesting, finally, to note the success of both these cases in the face of Billroth's direct condemnation of the treatment pursued (Surgical Pathology, vol. ii., p. 337), as interesting as it is to remember that the treatment which was written about so warningly by John Bell is that very one of extirpation most highly commended by Billroth.

Cheltenham.

THE BACILLUS OF SYPHILIS.[1]

By Dr. SIGMUND LUSTGARTEN,

FIRST ASSISTANT TO PROFESSOR KAPOSI IN THE DERMATOLOGICAL WARDS OF THE VIENNA GENERAL HOSPITAL.

TRANSLATED BY Dr. J. N. BLOOM, B.A., M.D.

SINCE Hallier's time, a period of almost twenty-five years, the virus of syphilis has been the subject of frequent communication and of almost constant discussion; but, nevertheless, the conviction is universal that none of these researches have even partially solved the question, because of their countless contradictions, inefficient methods, and errors that are easily recognised. And further, as my effort is not the continuation of any preceding one, I will not tax your time and patience by a review of the literature of the subject, but will at once detail my own observations, referring for the literature and development of the subject to a publication of mine shortly to appear.[2]

My researches with syphilitic products have led to the discovery of micro-organisms which until now were unknown, which are constant in their appearance, and which are thoroughly characteristic. They approach nearest in their morphological appearance and staining reaction to the bacilli of leprosy and tuberculosis, and, like these, are to be found in granulomata. By means of the method about to be given they appear as straight or curved, and sometimes irregularly bent rods, which are on an average from three and a half to four and a half micro-millimetres long, and from one-fourth to three-tenths thick. With a low power they appear uniformly smooth, presenting here and there a bulbous swelling at their extremities. With a homogeneous immersion lens (one-twentieth of an inch, Reichert) their surface appears irregularly undulatory, and slightly notched, yet in a manner such as to leave no doubt as to their rod nature. Within them we recognise, at equal distances from one another, oval, colourless, bright spores, from two to four in every bacillus. I never saw the bacilli lying free, but always enclosed in cells. These cells are from a trifle larger than, to double the size of, white blood-

[1] A paper read before the Royal and Imperial Society of Physicians of Vienna, on March 27th, 1885.

[2] Die Syphilis Bacillen, Wiener Medizinische Jahrbucher, first quarter, 1885; also as a brochure about to be printed by Braumueller, Wien.

corpuscles. They are round, oval, or irregularly polygonal, and sometimes show a central or eccentric oval nucleus in the shape of a light spot. The bacilli are to be found in them singly or in groups of from two to nine or more, sometimes intertwined, or, again, in irregular confusion. The cells containing bacilli occur sparingly in the midst of the infiltration, more often on the borders of the same in the apparently normal tissue immediately adjacent. I have observed them in papules embedded between the prickle cells of the rete Malpighii, and also in the initial lesion in the lumen of a large lymphatic duct. It seems to me to be beyond doubt that they possess the power of active locomotion—migratory cells. To obtain these results I had to employ a new method. Starting with the idea that bleaching measures would be serviceable in microscopic work, as well as in the arts and trade, I succeeded, after numerous fruitless attempts, in finding what I sought in permanganate of potash and sulphurous acid. In brief the method is as follows. Sections, which have been hardened in alcohol, are coloured in a solution of gentian violet (Ehrlich-Weigert),[3] from twelve to twenty-four hours at the ordinary temperature, and then for two hours at a temperature of 104° F. The section, in order to be decolourised, is first washed in absolute alcohol for several minutes, and is then, by means of a glass or platinum needle, conveyed into a watch-glass containing about three cubic centimetres of a 1½ per cent. aqueous solution of permanganate of potash. In this it remains about ten seconds. As a result, a brown flocculent precipitate of the hyperoxide of manganese is formed in the fluid, and also covers the section. It is then placed in an aqueous solution of chemically pure sulphurous acid, in which it is deprived of the hyperoxide of manganese, either instantaneously or in a very short time, dependent upon the concentration of the acid; it now appears entirely rid of its colouring matter in some places, while in others it is still deeply coloured. It is next washed in distilled water, and is again placed in the solution of the permanganate of potash, in which, as in the succeeding repetitions, it remains three or four seconds, and from which it is again conveyed to the sulphurous acid. When it appears colourless, which as a rule occurs after this procedure has been gone through three or four times, it is dehydrated in alcohol, rendered transparent in clove oil, and mounted in Canada balsam. Xylol Canada balsam is best. This method of decolourisation, to which, besides those already mentioned, the bacilli of leprosy and tuberculosis do not yield, not only permits the micro-organisms of syphilis already described to be brought to view, but is a characteristic staining reaction of them. The bacilli of syphilis, leprosy, and tuberculosis are not decolourised by my method. All other bacteria are. The bacilli of syphilis, however, are differentiated from those of leprosy and tuberculosis in that the latter are not decolourised by nitric and hydrochloric acids, whereas the bacilli of syphilis are. My method failed in the examination of splenic fever, typhoid, equinia, endocarditis ulcerosa, croupous pneumonia, various secretions of wounds, the contents of acne and scabies pustules, and also in the examination of normal tissue. I wish also to mention that my attempts to prove the presence of these micro-organisms in two chancroids were futile.

By means of the method just given I have examined sixteen cases of syphilis, which I will simply enumerate without going into particulars. Sections of two initial lesions; a lymphatic gland; three papules and four products of the tertiary stage; and further, the secretions of three initial lesions, and of the same number of moist papules. The result was a positive one in every case. The number of bacilli found varied. In general they were not very numerous. As regards the number, the age of the infiltration, and perhaps also the length of time since infection, are of importance. Thus I found in every section of two initial lesions, and of a periosteal gumma in a new-born child, one or more groups of bacilli, and here and there quite large groups among them; whereas in other cases a series of sections had to be examined before the undoubted presence of bacilli could be confirmed. According to my experience, the proof of the presence of the bacillus in syphilitic products is of equal diagnostic importance to that of the tubercle bacillus in the sputum.

Inasmuch as I have found, as a constant factor in undoubted syphilitic products of various kinds, a special kind of bacillus which differentiates itself in form and staining reaction from all those known up to the present time, and which therefore is a specific bacillus, and as we believe ourselves justified as regards other infectious diseases in assuming the constant occurrence of peculiar micro-organisms to be the cause of the disease, I maintain, as regards syphilis, that it is very probable that the bacilli which I have discovered are the carriers of the syphilitic virus. In addition to this specially important result the above-mentioned researches present several other theoretically and practically important facts and deductions, which I will briefly mention. The occurrence of bacilli enclosed in lymphoid cells whose power of locomotion, according to my before-mentioned observation, is beyond dispute; further, the occurrence of bacilli in the apparently healthy tissue lying nearest the infiltration; and, finally, and most especially, their discovery in the initial lesion in a closed lymph-duct—support the theory that the poison of syphilis is conveyed from the place of infection, first by the lymphatic system, and later through it into the blood-vessels. The occurrence of bacilli in the rete Malpighii is of great theoretical interest, and accords with the clinical observation that in certain cases syphilitic infiltrations need only lose their covering of horny epidermis (moist papules) to be contagious.

As I have shown bacilli of the same nature as in primary and secondary products to exist in typical gummata, we must look upon the latter, as indeed do the greater number of syphilologists, as specific syphilitic affections. Only a few writers have evaded the difficulty, inasmuch as they consider gummata to be the result of a specific cachexia, and not of a syphilitic virus, basing their claim upon a number of negative inoculations, and pointing out that syphilitic patients in the tertiary stage, as a rule, produce healthy—i.e., non-syphilitic—children. Recall to mind how long Ricord and his followers maintained the non-infectiousness of the products of the secondary stage, where the circumstances were so much simpler, because of the much greater frequency, the situation, and the nature of the manifestations. Further, I cannot understand why because one has some local syphilitic deposit he should not have healthy generative cells, and as a result should not produce healthy children. In heredity we must not forget that there are affections of the generative glands which have, perhaps, no subjective or clinical symptoms, and yet are followed by the production of diseased generative cells, or, at least, of spermatic fluid containing the virus. I know from a personal communication of Armauer Hansen, and I have been in a position to convince myself of it, that the testes of leprosy sufferers contain numerous bacilli in and between the seminal ducts, whether symptoms of disease of the testicles exist during life or not. In the future the question as to whether a given case is syphilis can only be affirmatively answered if the presence of the specific bacillus can be demonstrated.

In conclusion, I venture to hope that by continuous research, particularly in the cultivation and inoculation of the bacillus which I have discovered, etiological relation between it and syphilis will be so decidedly proved that none will deny it, and that a means will thereby be attained for successfully combating one of the saddest diseases of the human race. The experiences of the last few years in the successful attenuation of the virus of splenic fever and other infectious diseases warrant the hope that this expectation is not over-sanguine.

CLINICAL MEMORANDA OF TWO CASES OF CHRONIC VAGINITIS.

WITH REMARKS.

BY J. BRAXTON HICKS, M.D. LOND., F.R.S., &c.

CASE 1. *Vagina throughout covered with granulations: freely bleeding; complete recovery.*—A widow, of about sixty years, applied to me in consequence of a constant bloody discharge from the vagina. To the finger it felt velvety and granular, from os to vulva, bleeding on examination. The passage of the speculum caused much distress, and also bleeding; and it revealed the fact that from one end to the other the vagina looked as if covered by granulations as of a healing wound. The bleeding being severe, it was necessary to swab the whole surface over with tincture of perchlo-

ride of iron diluted with three or four times its weight of water. This restrained the bleeding, but gave some pain. Astringent injections of tannin were used daily, and every third day the speculum was passed, and a sponge saturated with the dilute tincture of perchloride of iron left behind, and subsequently withdrawn. As this gave much distress, injections of the same solution were used alternately with tannin solution (two drachms to the half pint.) The vagina was very sensitive, and all manipulations were attended with distress. But at the end of a month she was free from the bleeding, and in a few weeks more the vagina had resumed its normal state.

CASE 2. *Severe chronic vaginitis, with constant and free secretion of pus for over a year; treatment by injections hitherto useless; cured.*—This case, though not raw and bleeding like that just described, was with this exception the most severe of any I have seen. Throughout the whole passage it was felt to be granular and velvety, and through the speculum the mucous membrane was observed pouring forth purulent secretion in large quantity. Her age was about thirty, married. The condition had come on gradually, and there was no information leading one to suspect it to have had its origin in gonorrhœa. She had been under treatment by injections for a year before I saw her. She was admitted under my care into Guy's Hospital, and the vagina treated by means of the speculum. Various applications were used in succession: nitrate of silver (twenty grains to the ounce) once; swabbing with the iron solution, as in the former case; plugging with cotton having powdered tannin diffused in it every day for some time—all of which gave gradual improvement. After a fortnight I applied a drachm of anhydrous sulphate of zinc to the upper half of the vagina, plugging it below with cotton well greased. This caused considerable pain and some exfoliation of the vagina; but when it had passed over, the vagina made a quick recovery, aided of course by continued though milder injections, till she left the hospital cured in about a month from admission.

It is not often that cases of like severity are seen; but many present themselves of long standing, with a granular state of the vagina and pus-like discharge, defying the former treatment. But these are obstinate only for the reason that they have not been thoroughly and perseveringly treated; either the syringing of the lotion has been inefficient, applied in vertical posture, or by a sponge only to the vulva, it having never properly reached the upper portion of the vagina. The mode of application is of more importance than the kind of drug employed. The material should be in contact with the diseased membrane for ten minutes at the very least, if possible for an hour, or, better still, for twelve hours; if used as an injection, the patient should be in the horizontal position. But it is best in all cases to commence treatment with a good swabbing of the upper half of the vagina with strong carbolic acid or iodised phenol through the speculum, which should be retained for five minutes, and then the superfluous portion removed by dry cotton. Care should be taken that a portion be not drawn down to the vulva; if it should be, pain will ensue; this, however, can be removed by washing the part with wet cotton. Care also must be taken lest the carbolic acid run down the speculum on to the thigh or drawers, for if it does, a blister will ensue, and much grumbling likewise. This carbolic application might be repeated in about six or seven days, whilst twice every day an astringent lotion can be employed as strong as can be borne without distress. Of these there are numerous kinds:—Chloralum solution (one ounce to the half pint), tannin (two drachms to the half pint), boroglyceride (one ounce to the half pint), the old sulphate of zinc and alum lotion, tannin and alum mixed, tannin with iodoform, bichloride of mercury (1 in 1000). Preceding the use of either of these, it is well to employ an antiseptic douche, in order to wash away the secretions which would impede the action of the astringents. But I prefer to apply every three or four days, through the speculum, a stronger astringent than can be employed by the syringe—such as the tincture of muriate of iron diluted three times, strong chloralum; or, as recommended by Dr. Oldham, the walls of the vagina can be kept apart by a plug of cotton. An excellent way of effecting this is by using pledgets of cotton with a string attached, diffusing through them dry powdered tannin and alum with a little iodoform, passing these through the speculum and leaving them behind, and removing them after twelve hours. This can be done every second or third day. But I think that although the healthy vagina tolerates anhydrous sulphate of zinc and the tincture of muriate of iron or the weaker solution, yet when it is abraded or spongy these agents are apt to cause exfoliation of too severe a kind. The ordinary sulphate of zinc or alum, however, it will readily bear. These and similar expedients will, if continued steadily, almost always cure the condition as far as the vagina is concerned; but inasmuch as the mucous membrane of the uterus is often involved, attention must be directed to this part, or the vaginitis will recur.

George-street, Hanover-square, W.

MALT AS FOOD.

BY J. MILNER FOTHERGILL, M.D.

MALT as food has a great future before it. In the process of malting (which is a rapid germination) a distinct change is brought about in the seed. By the action of the diastase the insoluble starch is converted into soluble dextrine, which goes sweet in the mouth, so near maltose is it. The malt-combings, which are too rich in albuminoids for the brewer's purposes, are useful when malt is looked at as a food. Malt contains dextrine (some diastase), soluble albuminoids and phosphates, and when ground is an admirable food, while it is not expensive. Its taste is pleasant. It can be made into a pudding with an egg and some milk, and as such is palatable. It can be made a constituent of a milk pudding with advantage. When the brewer mashes his malt with hot water the diastase remaining in the malt converts the dextrine into maltose, which the yeast (next added) breaks up into alcohol and carbonic acid gas. The best white malt is not heated to more than 190°, as the diastase is acted upon injuriously by a heat above that point. Maltose is a sugar which does not readily undergo the acetous fermentation, and, therefore, as Dr. Mitchell Bruce points out in his "Materia Medica and Therapeutics," "will not give rise to acidity and dyspepsia." This is a great matter, as the cane sugar the cook adds to stewed fruit and milk puddings readily undergoes the acetous fermentation in many stomachs. The lævulose sugar of fruit, like maltose, readily undergoes the alcoholic but not the acetous fermentation. Maltose being less powerfully sweet than cane sugar, a greater quantity is necessary to sweeten the pudding. If the raw starch, semolina, sago, or tapioca be first put in the dish by itself, and placed in the oven for an hour (taking care not to have it burnt by the oven being too hot), not only are the starch cells cracked, but a certain conversion of the starch into dextrine takes place. If to this be then added an equal quantity of ground malt and some hot milk poured on, and the dish be allowed to stand a few minutes before being put into the oven again, the diastase of the malt acts upon the farina and converts it into dextrine and maltose. Dextrine and maltose being soluble, the pudding is very thin. Such a pudding is admirably adapted for invalids and dyspeptics, as requiring scarcely any digestion in the body. For those with whom ordinary milk puddings produce acidity, such a pudding is specially suitable. Ground malt may be added to fresh milk, and forms an admirable food in cases of acute disease. Baked flour perhaps goes better with meat broths, to which it gives a high food value. (Well-baked flour requires but a touch of saliva to render it soluble, and, added to meat broths and gravy soups, renders them very nutritive.) Malt, being sweet, goes better with milk, or apple-water, or tamarind-water, or lemonade, and gives us a food which being all but independent of the digestive act, can be most usefully employed in the sick room. Beef-tea (which alone is scarcely a food) and milk-and-seltzerwater pall upon the palate of the sick person, who craves variety just as do healthy persons. The adoption of ground malt as a food will solve for us one or two knotty questions connected with feeding people when the digestive power is feeble. Drinks like lemonade, made with malt instead of cane-sugar, would not only not go sour in the mouth and stomach, but would contain some phosphates and soluble albuminoids, and so form admirable beverages in pyrexial states. The many malt extracts now in the market are well adapted for such end.

Park-street, W.

PATHOLOGICAL RELATIONS OF FIBROUS DISEASE.

BY CHARLES DAY, M.R.C.S., L.S.A.LOND.

IN asking permission to record in THE LANCET a case connected with a certain group of diseases presenting somewhat peculiar features, I am reminded of a passage in the preface of Mr. Abernethy's work on the "Constitutional Origin and Treatment of Local Diseases," where, supporting his opinion of the advantages resulting from the report of cases, he observes: "If diseases, like other objects which we mean to delineate, be placed in various points of view and illuminated at pleasure so as to show distinctly their various parts, one accurate representation would suffice; but we see them obscurely, and as knowledge increases it seems like light shining from different places to illuminate the various parts of our examination." Thus I think it may be allowed that although the mere account of any case of morbid growth may not be susceptible of practical deductions available in the treatment of such disease, yet it may bring to our knowledge some accompanying phenomena hitherto unobserved, some special characteristic attending the case under observation, or the absence of the special physiological effects usually observed as resulting from the interruption to or cessation of the functions of some particular organ; and I think in the case I have to narrate there will be found points of sufficient interest to merit attention.

A lady, aged forty-five, married, no family, no miscarriage, menstruation having ceased without constitutional disturbance, of good height, fine figure, excellent physique and health, the only interruption being occasional attacks of biliousness attended with "sick headache," having had some fatigue and anxiety from attendance on a sick relative during the month of January, 1882, necessitating her getting up perhaps more than once in the night to see to the invalid in the adjoining room, was attacked with catarrh. As this subsided she complained of pain in the lumbar region and shoulders, which was regarded as rheumatism resulting from the cold. But in March inconvenience was experienced from a frequent desire to pass water, with difficulty in micturition, which increasing, an examination was made on April 2nd. There was no fulness in the hypogastrium indicative of any accumulation of urine, neither was there any tenderness. On passing the catheter not more than half a pint of urine flowed out; but although the quantity was small it afforded some relief. It was of a natural colour, sp. gr. 1019, and healthy to ordinary tests; no sediment, merely mucous cloud. After a short use of the catheter, the quantity removed each time being very small, the irritability of the neck of the bladder gradually subsided, but returned in a fortnight, causing painful efforts of expulsion, with the result of passing only a few drops at a time. This condition suggested the necessity of a more thorough examination, for although there was no sign of uterine trouble save the pain in the back, now of diminished force, the rheumatic character of which appeared to be confirmed by its attacking the lower extremities, the knees, ankles, and feet becoming very painful and swollen, the joint of the great toe presenting the usual appearance of gout, the patient at the same time being exceedingly apprehensive of and sensitive to anything touching the foot, yet treatment affording no relief, and nothing to be detected amiss with the bladder, it was evident the mischief was deeper seated. On passing the finger into the vagina it encountered an obstruction which felt like the os uteri, patulous, thickened, and corrugated, the first impression being that it was a case of prolapsus, but proved to be a fibrous growth springing from the sides of and encircling the ostium vagina. Passing the finger through the centre of this growth, the upper part of the vagina felt as though roofed in with a firm, smooth body—the uterus retroverted,—the walls of which were infiltrated with fibrous deposit, the whole being firmly adherent to the brim of the pelvis, the result no doubt of perimetritis. In the left labium was a fibroid perfectly round and smooth the size of a large gall-nut. In the left labium was a similar growth of smaller size, and on examining the rectum patches of induration could be felt. From the commencement to the end of the case there was not the slightest tendency to hæmorrhage, neither was there any discharge beyond a slight moisture, having no unpleasant smell save a faint odour somewhat resembling blood halitus. The progress of the case became very rapid, the growth in the vagina increasing until the central orifice was not larger than a No. 12 bougie. For the first two months the appetite was fairly good, but gradually became more and more impaired; then came on nausea, pain after food, and at last rejection of food by vomiting, unaccompanied with coffee ground sediment, merely the food returned. The urine—dating from the time when the catheter was first used, April 2nd, when scarcely half a pint could be withdrawn—became less and less in quantity until none could be withdrawn by that instrument; and from June 2nd to June 16th, when the patient expired, the secretion entirely ceased. During this time no inconvenience or any desire to void urine was experienced; neither was there any accompanying ascites, anasarca, or delirium, no evidence of toxic action from retained urea, unless the sickness and rejection of food could be referred to that cause, and not to malignant disease. The mind remained undimmed until the last moment arrived. Only for a short time in May did she complain of being disturbed by dreams, generally of an absurd tendency. No pain was present to add to the suffering of the patient and the distress of friends. The restless tossing to and fro, the very weariness of weakness as strength went out with the ebb tide of life is painful enough to experience or to watch. The emaciation became extreme and the skin assumed such a remarkable whiteness that it might well be taken to represent the reflection of "pallida mors."

There are several interesting features in this case, which, I think, may be pointed to as deserving consideration. Thus, the urine, which from an early period of the illness was scanty, diminished in two months from the small quantity of half a pint secreted in twenty-four hours to *nil*, and for the long period of fourteen days not a drop was secreted, or if secreted did not find its way to the bladder. If formed without passing from the body, one would naturally look for some corresponding systemic disturbance, some fluid infiltration into cellular tissue or cavity, some disturbed mental functions; but no, we observed none of these things. The stomach alone exhibited disturbed action, which might have resulted from that cause, but which I think there is far greater reason to believe arose from the same organic change which had invaded so many other parts of the body. Then the bowels became equally dormant without any abdominal fulness, so that ingesta being refused, feeding per rectum of no avail, and the natural outlets for refuse material being closed, one might almost describe the wasting of the body as a process of natural cremation through the lungs. The general state of fibrosis is also remarkable. The vulva, vagina, uterus, rectum, and doubtless the kidneys and stomach, were all impregnated with the same morbid material. The suddenness of its development in an apparently healthy person, its rapid progress, the absence of pain, hæmorrhage or any discharge, the want of a probable cause of its inception, and other circumstances previously referred to, all tend to give additional interest to the examination of the subject, and make us pause, as we too frequently are obliged to do, when endeavouring to trace the why and the wherefore, the *fons et origo*, of those many mysterious and manifold changes which constitute the deviation from that happy state called health, the lot of so few of us, to that other state designated disease.

In formulating a history for the case one is somewhat at a loss. What shall we say? Was it a constitutional cachectic diathesis, such as one might affix to cancer attributable to heredity? or caused by local irritation acting through nervous conduction on an anxious and depressed condition of the mind, inducing by some unknown agency such a change in the blood and eliminating organs as to result in the formation and general deposit of this special morbid material? The pathological position of fibrous disease I think is at the present unsatisfactory, and remains one of interest and doubt. Whether it is a disease *sui generis* of independent origin, unassociated with any disease, acting, as one may say, *loco parentis*, or whether it is essentially cancerous in its nature, and therefore connected with heredity, as held by Dupuytren, Ashwell, and Hodgkin (an opinion which may yet find upholders), is a wide subject for discussion and beyond the scope of this communication. But a case in which scirrhus of the breast existed with fibroid in the vagina, similar to one reported in a recent number of THE LANCET, leads not illogically to the view that, if not identical, there is much to favour the opinion that diseases so associated may result from a similar

constitutional idiosyncrasy capable of developing the one or the other. Inquiring into the family history of the patient, I could not hear of any member who had suffered from cancer in any form, but there had been gout, an attack of which manifested itself during the progress of this case.

Since reading Mr. Hutchinson's admirable Bowman Lectures, in which he traces a very intimate connexion between gout and various diseased conditions of the eyes, I have been impressed with the thought whether a similar relation may not be found to exist between that disease and other maladies, such as the one in point and others of a more malignant character. Additional force has been lent to the thought by the following circumstance. A family with a *long* history of gout has in the last two generations suffered but little inconvenience from it. The grandfather of the present generation was the last who experienced any *violent* attack. He was a "martyr to it," and crippled by it. He had four children, two sons and two daughters. Of these one of the sons only had two sharp attacks in middle life, remaining free up to the time of his death, which occurred at the age of seventy from cancer of the pylorus. Not one of his six children had any positive attack of this complaint (gout), although two of the sons had enlargement of the great toe-joint, but one daughter died of cancer of the breast, two sons of cancer of the bowels, and one son of cancerous ulceration of the leg. Cancer was unknown in this family when gout was in the ascendant. I can relate another case of a lady having gouty ancestry who became the subject of scrofulous ulceration of the glands of the neck. Some time after these healed a fibrous tumour formed in the uterus attaining a large size, unattended with pain or hæmorrhage, the health remaining unaffected. Sir James Paget also in his Bradshawe Lecture, "On Some Rare and New Diseases," like Mr. Hutchinson, tracking certain of them, more perhaps by history than pathology, discovers gout to be the source whence they spring, suggesting that as the typical form becomes less common, others hitherto unknown, or but little recognised, assume a prominence and attract attention by their increasing number, and though presenting at the first glance scarcely any feature by which their relationship would be suspected, yet, as he observes, "types vary in diseases as in species," and "the certainty and probable extent of this variation must seem the greater if we consider the mingling of diathesis in transmission from and through both parents." Thus he says, "In phlebitis we very often trace a variation from the customary type or standard of the very old and heritable disease—gout; in short, all the evidence of being one of the many forms of what is called incomplete gout." Osteitis deformans, rickets, and mollities ossium appear to have some relation to gout, "for some of the cases have known inheritance of gout," and are sometimes seen in "typically gouty persons."

It must be allowed that in searching after an "unknown quantity" a certain amount of guessing is permissible, and I think, with Sir J. Paget, "that it is a legitimate use of the imagination which may happily discern a way towards the truth." Hence, when we find fibroids and cancer associated or separated, yet blastemal formations developed in individuals of a typically gouty descent, it can scarcely be called "using the imagination to the furthest bounds of propriety" to suggest that they both owe their existence to the same dyscrasia. As one swallow does not make a summer, so deductions made from one or two cases may perhaps be regarded as only hypothetical, yet they may serve as a basis on which co-operation may establish a substantial structure of facts confirmatory of the view here suggested.

St. Mark's-square, West Hackney, E.

THE BRITISH OPHTHALMIC HOSPITAL, JERUSALEM.—On the 27th ult. a meeting in furtherance of the interests of this hospital was held in the Jerusalem Chamber, Westminster. The chair was taken by Sir A. H. Layard, and amongst those present were Sir Edmund Lechmere, Bart., M.P., Hobart Pasha, Sir Richard Temple, and Mr. Mocatta. The hospital was founded in 1882 by the English branch of the Order of St. John, and is chiefly intended to provide proper treatment for the peculiar diseases of the eye prevalent amongst the population. At present the hospital contains only four beds, and is maintained at an annual cost of £900, but double the amount is needed to carry on the work effectually.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas at mor borum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

CHARING-CROSS HOSPITAL.

CASE OF LATE CONGENITAL SYPHILIS OF THE THROAT; TREATMENT WITH MERCURY AND RECTAL ALIMENTATION; CURE; REMARKS.

(Under the care of Dr. BRUCE.)

THE diagnosis of the later manifestations of congenital syphilis is sometimes extremely difficult, especially when, as in the case which we publish, there are few, if any, signs in the patient himself of previous disease. In the absence of personal and family history in such cases it is sometimes necessary to wait until the effect of treatment has been tried. Although congenital syphilis at the age of this patient is not often fatal, still from the situation of the local lesion it may become so, and the treatment by nutritive enemata which Dr. Bruce adopted had without doubt very great influence in producing the cure of the case.

W. D——, aged thirteen, from Kent, was admitted into Charing-cross Hospital on Sept. 2nd, 1884, suffering from severe ulceration of the throat.

History.—He stated that his illness commenced about a month ago with inflammation of the lungs, followed within a week by the sore-throat, which has persisted ever since. From the first there was pain on swallowing and discharge from the mouth, and he immediately began to lose flesh. Previous to this illness the boy had been fairly healthy, but not robust. It was ascertained that as a baby (? aged two years) he suffered from rash and snuffles, and was treated at King's College Hospital. He has recently been living in an isolated house, in a healthy district, and the drains have been in good condition. He is the second of nine children; the eldest is alive and well, but all the others snuffled as babies, and several are dead. His father is alive and well. His mother miscarried five times.

Condition on admission.—The patient is a wasted, fair-complexioned boy, confined to bed. He lies with the mouth open, in obvious distress in the throat, and speaks with a very indistinct nasal voice. The skin is of an earthy tint and very dry, without rash or œdema. The uvula and posterior border of the soft palate have entirely disappeared, leaving an ulcerated margin; anterior to this the palate is red and shiny. The posterior wall of the pharynx is entirely occupied by a foul greyish-yellow slough, which extends upwards and downwards as far as the eye can reach. There is no swelling of the glands of the neck. The patient takes food indifferently, owing to dysphagia; part returns through the nose, and part is rejected by vomiting. The liver and spleen are not enlarged; bowels confined. A hacking cough ends in expectoration of mucus and sloughs detached from the pharynx, which contain no tubercle bacilli. The physical signs connected with the lungs, heart, and abdomen are normal. Pulse 74, regular, weak; urine scanty, sp. gr. 1033, without sugar or albumen. Sleep good.

Diagnosis.—Syphilitic ulceration of the throat, congenital.

Treatment.—Mercurial ointment (half strength), a portion as large as a hazel nut to be rubbed into the adductor region of the thigh daily. Pharynx to be rubbed with solution of nitrate of silver, twenty grains to the ounce. To be fed by nutrient enemata of beef-tea, yelk of egg, and brandy, four times a day, whilst allowed to take what food he cares to attempt by the mouth.

Progress of the case.—Sept. 12th: Very little but still decided improvement; rectum becoming irritable. Two minims of tincture of opium added to each enema. Little change in throat. Strength of silver solution increased to forty grains to the ounce. A little brandy taken by the mouth.

16th.—Marked improvement; the patient looks more lively and the throat is less foul, the soft palate looking more healthy, its posterior margin more raw, and the pharynx less thickly covered with sloughs. The enemata are better

retained; a little food, both solid and fluid, taken by the mouth. Urine very scanty and high-coloured.

19th.—Strength increases; but little change in throat since the 16th. Most of the enemata retained; very little food can be swallowed. Spirits improving; voice still thick and nasal. Throat to be swabbed out twice a day with silver solution, sixty grains to the ounce.

24th.—Marked improvement. He sits up for an hour, and is more active and cheerful. No dysphagia; no regurgitation of food; enemata all retained. Back of pharynx presents only a thin slough; posterior part of soft palate merely reddened.

26th.—Moves about the ward. Throat greatly improved, the red base being seen through the grey surface of the pharynx, and the edge of the soft palate looking healthy. Can take most of his food by the mouth, but has still four nutrient enemata daily. Strength of silver solution reduced. Gargle of chlorate of potash ordered. Urine more abundant.

30th.—The slough has entirely disappeared from the pharynx. Strength increased, but three pounds weight said to have been lost within three days.

Oct. 3rd.— Throat now clear. Further loss of two pounds, but strength increased. Slight salivation. Mercurial reduced to one half.

7th.—Weight has increased two pounds. Salivation continued. Mercurial inunction stopped.

10th.—Nutrient enemata stopped. Meat diet by the mouth.

14th.—Steady increase in body weight. Still salivation.

17th.—To take syrup of iodide of iron.

21st.—Has gained two pounds weight in three days. Great improvement in general appearance. Adhesions forming in pharynx, with small points of ulceration.

Nov. 19th.—Discharged cured.

Clinical remarks by Dr. BRUCE.—This case was of considerable interest from its nature, and from a certain degree of difficulty attending its diagnosis; chiefly, however, in connexion with the details of treatment. Active congenital syphilis at the age of thirteen is not so common but that it deserves record, and its diagnosis as a matter of fact may be very far from easy at first. In the present instance the previous personal history and the family history of infantile snuffles were not obtained for several days after admission, and during this time the true nature of the illness was the subject of some discussion. The question of tubercular ulceration was raised, but the absence of swelling of the neck alone went far to dispose of the suggestion. The best immediate evidence of the correctness of the diagnosis of late congenital syphilis was the result of the severe treatment to which the patient was subjected. He was at once put upon mercury. But here a great difficulty arose; the patient could not swallow. Dr. Bruce urged upon the students the absolute necessity of ensuring an abundant supply of nourishment to the tissues whilst a powerful alterative like mercury is being allowed to act upon them. It was contrary to all sound clinical rules to administer mercury to a starving child, and a patient unable to swallow was virtually starving; but just as certainly the patient would shortly die of syphilis. Feeding *per oram* was therefore given up definitely, and regular nutrient enemata ordered instead, whilst the patient was permitted to attempt to eat occasionally small portions of nutritious food. The method proved successful. A stronger solution of nitrate of silver might have been used from the first for swabbing out the throat, but the shock attending free cauterisation of the whole pharynx might have been too great in the prostrate condition of the patient. As occasionally happens, the rectum, which was irritable at first, came to retain the nutrient enemata very well. There was free salivation for a time, although the mercury was reduced, and soon omitted when the mouth became tender. Another curious fact was that the boy continued to lose weight, whilst his general appearance and strength and the local disease were all steadily improving.

DUNDEE ROYAL INFIRMARY.

ABDOMINAL SANGUINEOUS CYST; ASPIRATION; RECOVERY; REMARKS.

(Under the care of Dr. SINCLAIR.)

J. G——, aged fifty-one, flaxdresser, was admitted on May 14th, 1883, with the following history. About two months previously he observed a smooth round swelling just below the umbilicus, which rapidly increased in size; it caused no discomfort except that arising from its rapidly increasing bulk.

On admission, a rounded swelling, quite smooth to the touch, could be made out in the umbilical region of the abdomen, but extending slightly into the other regions. It was of firm consistence, and appeared to be adherent to the anterior wall of the abdomen (the umbilicus not being movable over it). No fluctuation or impulse could be elicited. There was no bruit on auscultation. The tumour occupied the umbilical part of the epigastric, hypochondriac, and right lumbar regions, and a very small portion of the hypogastric region. It was clearly separable from the hepatic dulness by a narrow resonant line, and it did not move with respiration. The hepatic and splenic dulness were of normal extent; no abnormal signs were discovered in the lungs; the cardiac dulness was normal, but the sounds were weak; tongue slightly furred but moist; appetite good; bowels constipated; temperature 99°; pulse 70, weak; respiration 28; urine pale, slightly acid, sp. gr. 1018, no albumen.

17th.—Hypodermic needle was inserted into tumour, and a syringeful of dark sherry-coloured fluid was readily withdrawn. The fluid contained nearly 50 per cent. of albumen, abundant red blood-corpuscles, and some amorphous masses. No echinococci or hooklets. Sp. gr. 1020.

21st.—The tumour was aspirated in its centre, and sixty ounces of fluid were withdrawn, of the same character as that removed by the hypodermic syringe.

22nd.—The patient complained of sickness yesterday after the operation. No trace of tumour.

June 2nd.—Patient got up.

6th.—He was dismissed in good general health, the tumour having entirely disappeared.

Remarks by Dr. SINCLAIR.—I can find no description of a similar cyst in Bright's classical memoirs. One, in some respects similar, is described by Bauer in Ziemssen's Cyclopædia.[1] It terminated fatally after two tappings. In THE LANCET of May 5th, 1883, Dr. Bristowe described two cases of abdominal cysts which resembled the one just described in the rapidity of growth and sanguineous contents. The first he concluded to be probably either a simple cyst of the spleen or a distended kidney, more probably the latter. The second had a much larger history, and was found on post-mortem examination to have been a sanguineous cyst resulting from a round-celled sarcoma. Dr. Clifford Allbutt has described a case[2] presenting some points of resemblance to mine as regards its contents; but it had a rather higher situation, required three aspirations, re-formed subsequently, and then disappeared after an attack of diarrhœa and colic. Dr. Oliver's case,[3] which occurred in a female, yielded 148 ounces of blood-red fluid on the first, and 84 ounces of similar fluid on the second, tapping, made a much slower recovery than mine, and was considered by him to be probably a hæmatocele of ovarian origin. The case described by my friend, Dr. Reid, and which was watched with great interest by us all, was clearly, I think, unconnected with any of the solid viscera of the abdomen. That it was not hydatid was evidenced by the absence of hooklets on careful microscopical examination. I can see no ground for considering its origin malignant. The impression is that it was a cyst of peritoneal origin, possibly owing to a traumatic cause, as the patient is a man of intemperate habits. I saw the man some time ago, a year after dismissal, and found him in good health, and quite capable of performing his usual work; but I thought I discovered some traces of reaccumulation. As cases of this kind are of great interest and rarity, I shall keep a watch on the patient, and report his further history should the disease return.

DOUBLE THORACIC ANEURYSM; DEATH; AUTOPSY.

(Under the care of Dr. SINCLAIR.)

For the following notes we are indebted to Mr. J. Mackie Whyte, M.A., M.B., house-surgeon.

J. W——, aged forty-nine, a tall well-built man, employed as a labourer in a jute works, was admitted on Feb. 14th, 1884, as an urgent case. His history was that he had been subject to pain in the chest since the middle of December, 1883, when he fell downstairs while drunk, and received a scalp wound, but no other external injury. The wound healed, but the pain in the chest became worse, catching his breath. For the past fortnight his voice had been hoarse, and he had had a troublesome cough, with inability to expectorate the mucus, which caused a disagreeable rattling noise. Had been in the army; while there he had acquired syphilis; otherwise previous health had been good.

[1] Vol. viii., pp. 338–39.
[2] THE LANCET, July 7th, 1883.
[3] Ibid., Oct. 11th, 1884.

On admission, he was in a state of great dyspnœa; he spoke in a hoarse whisper; cough of a ringing character; throat dry; no difficulty in swallowing; pupils equal; radial pulses equal, 54 per minute, regular; pain in region of heart apex on any exertion; a "gripping" pain, constant, in interscapular region; general præcordial heaving, and epigastric pulsation; apex-beat in fifth space, nipple line; systolic murmur in mitral and aortic areas, loudest in mitral; second sound accentuated, with a distinct pump-valve character, best marked in aortic area; dulness in upper part of thorax extending from one inch to right of manubrium across sternum for five inches. This dulness was continuous with the cardiac dulness. There was also dulness in the left interscapular region, opposite the spine of the scapula and a little below. The second sound was distinctly heard accentuated over this area. Physical signs of lungs normal, except for occasional bronchitic wheeze. Examination of larynx showed paralysis of left vocal cord. Urine normal. Great improvement followed the treatment, which consisted of rest in bed and administration of bromide and iodide of potassium internally. On May 19th the patient was sent to the Dundee Convalescent Home, but was refused admittance, as he had got drunk on the way.

He presented himself again at the infirmary on Oct. 29th, as bad as ever. Had been employed chiefly in carrying bales of jute; always felt a "gripping" pain in the chest when lifting. Physical signs much the same as when in the infirmary before. Left radial pulse smaller than right, 66 per minute. Improvement was slow, and relapses of dyspnœa occurred. Towards the end of November breathing was very noisy.

On Dec. 10th, about 10.15 A.M., the patient, who had been sleeping quietly, was seized with a paroxysm of dyspnœa. There was laryngeal stridor, like cock-crowing; the face became blue, and he sprang out of bed, saying he was dying. In about five minutes he expired. His face became pale after death.

Autopsy.—Right pleura adherent in whole extent; some tough adhesions also in left, especially near the upper part. Thoracic contents removed in mass with some difficulty, on account of close adhesions to the vertebræ. There had been no escape of blood from the vessels. Heart empty of blood; both auricles dilated, walls very thin; left ventricle considerably hypertrophied. Aortic valve incompetent; no vegetations but dilatation, circumference being three inches as measured when laid open. Mitral valve somewhat dilated. Ascending part of aorta showed fusiform dilatation, circumference four inches. Wall athoromatous, with calcareous deposits. The dilatation extended as far as the origin of the left common carotid; the vessels arising from the arch were not themselves involved. Thus the transverse portion towards its termination was of normal calibre, but at the bend it suddenly dilated into an aneurysm larger than a cricket-ball. This consisted of two parts, separated by a constriction; the anterior had the same lining as the aorta, with which it was obviously continuous, the posterior had a wall which was dark in colour and rough, and was largely filled by a laminated organised clot. The pressure of this part had caused deep erosion of the bodies of the third, fourth, and fifth dorsal vertebræ, in front and on the left. The left vagus was traced over the transverse part of the arch and its branch, the left recurrent laryngeal was followed round part of the aneurysm, where it was thickened and irregular, and up alongside the trachea. Neither trachea nor œsophagus showed any effects of pressure; the latter was close to the aneurysm. Lungs much congested; also the abdominal viscera. Fibrous adhesions from old peri-hepatitis all over the liver.

Remarks by Dr. SINCLAIR.—The history of this case clearly suggested aortic aneurysm; the symptoms on admission pointed most distinctly in the same direction; and the physical signs left no doubt that we had before us a case of aneurysm of the arch pressing on the left recurrent laryngeal nerve. In every respect, then, the record was singularly complete and satisfactory up till the moment of the patient's death, which occurred quite suddenly. The autopsy showed that it was not due to rupture of the sac, as might have been anticipated. In the absence of any other quite satisfactory explanation, I suppose paralysis of the heart may be suggested as the most likely cause. The case is interesting also from the fact that there were two distinct aneurysms, separated by a short interval of aorta of normal calibre. This circumstance alone seems to me to be of sufficient interest to justify its being placed on record.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Discussion on Cholera.

THE adjourned discussion on cholera was held, and the debate concluded, on Tuesday last, Dr. George Johnson, F.R.S., President, in the chair.

Dr. HENEAGE GIBBES said that he fully agreed with everything that Dr. Klein had said. In acute cases of cholera, instead of a pure cultivation of comma bacilli in the lower part of the ileum, comma bacilli were to be found few and far between. Cultivations of the small straight bacilli in a large number of test tubes proved that these bacilli were not young comma bacilli, but belonged to a distinct species, for they grew in a totally different manner, did not liquefy the gelatine, grew on the surface chiefly, and were not motile. That the comma bacilli were not discovered in the tissues was certainly not due to defective staining. He had used every possible staining fluid and combination of fluids, but had found no comma bacilli, in the intestinal walls. A case of infantile diarrhœa showed a more pronounced morbid change in the intestines than exists in cholera, and so the intestinal lesion could not account for the collapse of cholera. In one case in Lieberkühn's follicles many putrefactive bacilli were present, and this specimen was shown to the Society.

Sir GUYER HUNTER said that, as he understood, Koch had shown that the comma bacillus stood in the relation of cause and effect to cholera. He did not believe that cholera was dependent on the action of a germ. He referred to the characters of the last outbreak of cholera in Egypt and in France as proving his contention. The report on Egyptian cholera presented to Her Majesty's Government also maintained the same views. He considered that cholera had been proved to be non-contagious. A surgeon, writing in the *Practitioner* of July, 1875, advised the injection of chloral hydrate in doses of 10 grains in 100 minims; this treatment in his hands had been so disastrous that he was compelled to stop it. He did not agree that opiates increased the danger from collapse; any premonitory diarrhœa should be treated by opium and stimulants. He believed cholera to be due to a series or combination of conditions. If the germ is killed by decomposition, then cholera ought not to exist in localities where filth and garbage abound. Strict hygiene was the only way to prevent the occurrence of cholera. Any form of ill-health predisposed to cholera.

Dr. PYE SMITH spoke of the choleraic discharge, and agreed with Cohnheim that this was not of inflammatory origin. In cases of cholera sicca large quantities of detached epithelium were present in the intestines, but this was probably the result of post-mortem change. Moreau obtained a "paralytic secretion" by section of the mesenteric nerves, and the large quantity of effusion thus obtained coincided in many respects with the choleraic discharge. The nervous influence was conveyed, not through the splanchnics or vagus, but by way of the smaller mesenteric ganglia derived from the solar plexus; and excision of these ganglia led to the production of a large intestinal effusion. He was in accord with the generalisation made by Gaskell, to the effect that the exciting influences were conducted by means of grey nerve fibres, whilst inhibitory influences passed along the medullated nerve fibres.

Mr. MACNAMARA said that no epidemic was known to have arisen outside the confines of British India. The statements made by Klein with regard to infection were in absolute variance with the conclusions of all previous workers. It was remarkable that the comma bacillus should correspond to the characters of the contagium as described by Parkes—viz., that it was destroyed by acids, that its life in water was very brief, and that the conditions under which the water was placed must be of a certain kind. He referred to the case in which choleraic discharge polluted some water of which nineteen individuals drank, and within thirty-six hours five of these persons were dead of Asiatic cholera. He quoted many circumstances and incidents tending to prove that cholera was a contagious disease. From his observations made on individuals dead of cholera, he could not agree with the views expressed by the President on the existence of spasm of the pulmonary

arterioles, for he had not found distension of the right side of the heart. He was not successful in the treatment of cholera by castor oil; he had seen the best results by the use of opiates and astringents.

Dr. JOHN MURRAY thought that the habitat of the poison of cholera was the mucous membrane of the intestines: it first caused paralysis of the sympathetic, which prevented the excretion of effete material. The left ventricle was sometimes occupied by a coagulum, which was black at first, but tended to become decolourised. A feeble fluttering pulse was the sign of the formation of a clot in the heart. In his experience laxatives were most dangerous, and in this he was corroborated by the experience of observers in all parts of India. Any remedy which promoted the secretion of the bile and gastric juice was of value in the early stage of cholera. Transfusion of hot saline solutions caused the spasm of the pulmonary arterioles to pass away.

Dr. HERON reverted to the question of the bacteriology of cholera. From the beginning of the growth of the various comma bacilli, it was possible to distinguish Koch's bacillus from all the others. All the comma bacilli could be distinguished from one another. In cholera nostras the comma bacillus of Finkler would be found, and not the bacillus of Koch. He thought that cases of cholera might be distinguished from cases of cholera nostras by a cultivation of the comma bacillus; the mode of growth was so different. He said that Koch and Klein agreed that there was a comma bacillus peculiar to cholera, which was to be found nowhere else. The comma bacillus of Lewis was different from that of Koch. He had examined eight cases of tubercular diarrhœa without discovering the comma bacillus of Koch, and so could not agree with Klein's statement on this point. Koch and his staff of assistants held themselves in readiness to go to any part of Germany in order to determine by bacteriological research whether a case submitted to them was one of Asiatic cholera or not. We were indebted to Koch for this possibility of diagnosing true cholera, as we were for so many other discoveries in medical science.

Dr. THIN said that many people certainly believed that the comma bacillus of Koch could be found in other diseases and conditions besides cholera; he thought that Dr. Klein, or those who reported him, were responsible for this impression. He narrated circumstances which seemed to show that hygienic conditions, and kinds of food, such as lettuces manured with human excreta, did exercise an influence in the production of cholera.

Dr. J. JOHNSTON had had much experience of cholera at Shanghai. Cholera prevailed when the fruit season began. Cholera was predisposed to, if not caused by errors in diet, carelessness in the use of purgatives, and other forms of indiscretion. Drinking water was certainly active in the causation of cholera. Evacuant treatment in his hands was decidedly harmful.

Mr. SEDGWICK said that at the time he wrote his work on the Urinary Secretion in Cholera and Diarrhœa he was not aware that urea was a binamide of carbonic acid; knowing this he had less difficulty in understanding how the preformation of carbonic acid in the tissues and blood should continue and the preformation of binamide of urea should cease through the defective oxidation of the blood. M. Doyère had investigated the chemistry of respiration in cholera. In normal respiration there were 44 vols. of CO_2 discharged in every 1000 vols. of expired air to every 165 vols. of oxygen taken up. The relative diminution in the amount of carbonic acid in the expired air in cholera was accompanied by an increase in the proportion of the oxygen. In collapse about three-fifths of the normal quantity of CO_2 were discharged, and the oxygen absorbed was largely in excess of the carbonic acid eliminated. In cholera the mammary secretion and all other secretions having to do with the generative organs were not interfered with. Encysted dropsy of the ovaries suffered little or no diminution in amount. Anasarca might disappear completely, as Dr. Barlow had shown, in cases which recovered. Menstruation was not delayed or checked in cholera unless the period were about to commence. The liquor amnii and urinary secretion of the fœtus were not stopped. He did not agree with the view expressed by Mr. Simon, that cholera always proved fatal to the fœtus, and quoted some statistics of a French author in this regard.

Dr. MACLAGAN believed that the poison of cholera was a micro-organism, for nothing but a living thing could reproduce itself. It was a peculiarity of parasites that each had its own nidus. Cholera had its relationship with the acute specific fevers. The nidus in cholera was the epithelium of the internal viscera, and especially of the small intestine. He did not agree that the shedding of epithelium was a normal post-mortem change. The collapse of cholera might be likened unto the rigor of onset of the specific fevers.

Mr. SCRIVEN could not understand how the viscidity of the blood in cholera could not be due to a loss of water, for the blood had unlimited power of appropriating fluid from all the tissues. He could not agree with the views of the President in this respect. He dwelt at some length on the treatment of the various stages of cholera.

Dr. LOWNDES said that diffusible nutritive fluids, like Liebig's raw soup, in small doses every half-hour, were most valuable in the treatment of cholera.

Dr. JOHNSON, in reply, maintained that the distension of the right side of the heart was a fact testified to by Dr. Edmund Parkes before his own observations and experiments had been made. Dr. Sutton, in the fourth volume of the London Hospital Reports, confirmed the same observations. The right side of the heart was distended and the left nearly empty in cases of cholera. He said that chloral hydrate did not abolish arterial spasm. He contended that spasm of the pulmonary arterioles explained the greater number of the phenomena of collapse, and still maintained the accuracy of his views as to the evacuant treatment in the early stages of cholera. He fully recognised the existence of cholera so severe that no treatment could avail.

CLINICAL SOCIETY OF LONDON.

Treatment of Spina Bifida.—Choreiform Movements in Infantile Spasmodic Paralysis.—Carcinoma and Calculus of the Bladder.—Pistol-shot Wounds.

AN ordinary meeting of this Society was held on the 27th ult., Mr. Thomas Bryant, F.R.C.S., President, in the chair.

Mr. MAYO ROBSON (Leeds) read a paper on a Series of Cases of Spina Bifida treated by Plastic Operation. He described four cases on which he had operated:—Case 1. A. S——, aged six days, was the subject of a spina bifida the size of an orange; operated on Oct. 26th, 1882. The child lived and thrived for a year, when it died after a day's illness from teething convulsions. The site of the tumour presented only a linear scar. The interposed periosteum had not formed new bone. (The excised sac was shown to the Society.) Case 2. Mary A——, aged eighteen days, a puny, ill-developed child, with a large spina bifida in the lumbar region; the sac was thin and translucent quite to the margin of the tumour, and the skin around inflamed. It was all excised except two narrow portions, which were sufficient to form meningeal flaps, these being covered in by skin flaps obtained by separation and sliding from the lumbar regions. The wound healed by first intention, but the child died from a continuation of the marasmus present before operation. At the autopsy the whole lumbar spine and part of the sacrum were bifid. There was no meningitis. (Specimen was shown to the Society.) Case 3. L. J——, aged sixteen, the subject of spina bifida in the lumbar region, the size of a fœtal head, was admitted to the infirmary to have tenotomy performed for talipes. The sac of the spina bifida began to inflame the day after admission, before any operation had been done, and produced high fever and severe head symptoms, threatening life. It was aspirated eight times between November 13th and December 9th, the last three aspirations yielding pus. She was rapidly losing ground and apparently sinking, so on December 11th Mr. Robson excised the sac after reflecting the skin by crucial incision; the cavity was drained for a few days. The head symptoms were at once relieved, and she recovered rapidly, being discharged cured twenty-four days after operation, with the wound quite healed, and only a scar where the tumour had been. (Patient shown to the Society.) Case 4. D. C——, aged seven, had a spina bifida in the lumbar region, seven inches and a half in circumference; sac thin and inflamed at fundus; skin dissected from sac, and redundant sac and integument removed; suture of meninges by catgut, and of skin by wire. The wound healed by first intention, and the patient was discharged cured thirteen days after operation. The child was shown to the Society six weeks after with a linear scar where the tumour had been. All the operations were performed strictly antiseptically, the eucalyptus atmo-

sphere being used instead of the spray. The points to which he would draw attention are—1. The principle of closing the meninges by bringing together two serous surfaces, as in peritoneal surgery, and superimposing separate skin flaps, the meningeal and skin lines of the suture not being apposite. 2. The great importance of observing strict antiseptic precautions, as a septic condition would probably end in the same way as these cases usually do when they spontaneously ulcerate—viz., by meningitis and convulsions. 3. The success attending the plastic operation in cases which are absolutely not amenable to any other form of treatment—e.g., where the coverings are thin, or the opening into the spinal canal large. 4. The possibility of transplanting periosteum, and its capability of surviving, as in the case read first. One may hope that the use of human periosteum—"e.g., from a recently amputated limb"—will give better results. 5. The successful issue of Case 3, where, although the sac was acutely inflamed, its complete removal with efficient drainage effected a cure. This case presents several points of pathological importance—e.g., (*a*) The rise of temperature without septicity apparently due to tension of, or pressure on, the great nerve centres. (*b*) The great relief given by aspiration. (*c*) Suppuration in the sac, possibly due to simple tension, probably not due to septicity, as the fluid was quite sweet on every occasion. (*d*) The entire absence of brain symptoms after operation, although the pressure on the great nerve centres must have been considerably interfered with during the time of healing of the wound. Mr. Robson suggested the following as a practical classification of cases of spina bifida for purposes of treatment—(1) Where no operation can or should be done. (2) Where no operation need be done. (3) Where an operation should be done. Class 1 (*a*) Where the deformity is very extensive, as in fissure of the whole or a considerable portion of the vertebral canal. (*b*) Where there is complete paraplegia. (*c*) Where the sac is large, the fissure extensive, and the coverings excessively thin up to the edge of the tumour, and no skin can be obtained to cover the meninges. But that such extreme examples even may stand a chance of cure is proved by Case 2. Class 2. Where nothing need be done. Where the sac is small and the coverings are so dense and firm as to form a good pad over the opening in the spinal column. Class 3. Where some operation should be done. (*a*) Where the sac only communicates with the spinal canal by means of a small opening; here it is a simple matter to dissect off the skin, expose the neck of the sac, ligature it by means of one circular ligature, and cut off the redundant meninges, bringing the skin over so as to have the line of skin sutures quite at the side away from the pedicle. Such an operation was performed by Mr. Ed. Atkinson, one of Mr. Robson's colleagues at the Leeds Infirmary. (*b*) Where the sac has a good skin cover and communicates with the spinal canal by a large opening, it is quite easy to perform the operation described in Case 1, carefully closing the meninges, and, if possible, placing the line of skin sutures away from the meningeal line of union. Such cases have been operated on successfully, not only by Mr. Robson but by Prof. Jessop, U.S.A. Human periosteum might be placed between the meninges and skin, but Mr. Robson is not at all sure that a thin plate of bone, if formed, would be very serviceable. If the expanded neural arches be large, he thought it might be feasible to bend them towards the central line, and by uniting them with thin silver wire, obtain a truly physiological closure of the spinal canal. (*c*) Where the coverings are excessively thin up to the margin of the tumour, as in Case 2, the operation is more difficult and uncertain, as the skin can only be obtained by a process of sliding from contiguous parts, and the tension necessarily present is not conducive to healing. (*d*) Where the spinal cord or the nerves are blended with the sac, he advises excision of portions of the redundant meninges at one or more places between the nerves, replacing the nervous structures in the spinal canal, and bringing over the skin cover; free drainage should be kept up between the membranes and integuments, or if this could not be done, the membranes might be punctured, the collapsed sac, with the nerves intact, being placed in the canal, and the skin cover made as before. It is important to remember that a silver or a leather shield should be worn over the site of the operation in order to protect the parts from injury, and to prevent the cicatrix from stretching or giving way.—The PRESIDENT said that the surgical treatment adopted by Mr. Robson gave surgeons an additional means of dealing with cases of spina bifida. He considered that there was not sufficient evidence to show that the method of injection was one which could be regarded as a good surgical procedure. He congratulated Mr. Robson on having been so successful in the four cases which he had treated. It was remarkable that the nerves were not involved in a large number of cases of spina bifida. The last suggestion with regard to the treatment made by the author was a good one. No doubt the committee now sitting on spina bifida would carefully consider the method of treatment advocated by Mr. Robson.—Mr. R. W. PARKER joined with the President in congratulating Mr. Robson on the successful results of his plan of treatment, yet he could hardly think that it would lead to results very much superior to those obtained by treatment of a less operative kind, for the lesion was a very profound one in many cases, such as no operation could rectify. An examination of the specimens in the London museums showed that the cord and its nerves entered the sac in upwards of 95 per cent. of all cases, a fact which itself contra-indicated excision of the sac wall; but if the sac wall were simply tucked in after the normal skin around its base had been detached, and, after more or less evacuation of the fluid, a satisfactory result might be obtained. The Society's subcommittee were just about to present their report, and, as a member of that committee, he would refrain from anticipating the conclusions which would be expressed in the report. He was sure Mr. Robson's paper would receive every attention. He might add that cases of cure by injection had been reported in which, as was found on post-mortem examination years later, the cleft in the spinal column was found to be very extensive. In the infant shown, although the sac was absent, there appeared still to be a soft fluctuating swelling over its former site.—Mr. RICKMAN J. GODLEE said it was evident that in the plastic operation of Mr. Robson there was no great risk of producing meningitis, and in this respect it seemed almost a safer method than injection with Morton's fluid. Reference was made to two cases which he had recently observed in which the injection of Morton's fluid was followed by the development of meningitis. In one case the child had convulsions, hemiplegia, and vesical paralysis; cystitis set in later on; the patient ultimately died. The occurrence of severe symptoms after surgical treatment might in some way be related to the frequency, with which some part of the spinal cord was involved in the sac, though in many cases the filum terminale could be the only part involved, and this was comparatively an unimportant structure. He spoke of a post-mortem examination which he had recently witnessed on a case of spina bifida in which the three or four lower sacral nerves were involved, and arose from points slightly to one side of the middle line, which he supposed was occupied by the expanded filum terminale of the cord. He said that Mr. Robson's was a line of treatment that would have to be carefully considered.—Mr. R. W. PARKER said that the spinal cord extended the whole length of the spinal column in intra-uterine life, and there was practically no filum terminale. Moreover, he had never succeeded in detecting the filum terminale in any specimen that he had examined.—Mr. MAYO ROBSON, in reply, believed that there were many cases of spina bifida into the formation of which no part of the spinal cord or nerves entered. It was impossible for distension of the filum terminale to give rise to the kind of sac which he exhibited, and which he had removed from one of his cases. With regard to the injection of Morton's fluid, in all the cases in which he had seen it used the result was fatal.

Dr. W. B. HADDEN read notes of a case of Choreiform Movements Supervening in Infancy and of Congenital Origin. The patient was a female, aged twenty-two; there was nothing to note in the family history, except that a sister died of fits at the age of ten months. The mother had had no miscarriages, but was said to have suffered from albuminuria for two months before the patient was born. Labour came on at full time, lasted twelve hours, and no instruments were used. Very soon after birth the child's head used to fall back, and she did not sit up like other children. There were no fits and no head injury. She never walked better than she does now. Movements were first noticed when the child was aged seven months, but did not attract serious attention until the age of two years. They have persisted ever since. She began to talk between the age of two and three years. Catamenia appeared at the age of fifteen, have always been regular, but scanty and painful. Patient is a short, stout, well-developed girl; is quite intelli-

gent, reads fairly, but cannot write because of the condition of her hands. Her head is large and flat, but symmetrical; palate hard and a little arched; no deformity of spine. Movements very slight when lying down, and absent during sleep. They are at once noticeable on attempting movement, or if the patient be excited. The face and upper limbs are mainly affected. On trying to speak the face becomes contorted. The angles of the mouth are retracted, upper lip and alæ nasi raised, the forehead wrinkled, the eyelids partially closed. Hence, there are various and rapidly succeeding grimaces. An appearance of gaiety is followed by a frown, by a sniff of disdain, and by a momentarily lacrymose aspect. The speech is interrupted and the words brought out explosively. The muscles of the back and abdomen are unaffected. There are slight movements of the tongue. The fingers are flexed at the metacarpo-phalangeal joints, and extended at the phalangeal. But this position is not fixed. Fingers are often expanded, and there are simultaneous to-and-fro movements, suggesting athetosis, but more rapid and various. Some rigidity exists about the muscles of the arms and forearms. The muscles are well developed, and respond well to galvanism. Her grasp is feeble. Her legs are short, well developed, and as she lies in bed have very fair power. She cannot stand or walk without help. When supported she shuffles along, the legs overlapping, and the knees rubbing together, and the thighs being adducted. There is much resistance to passive movement of the legs; the tendon reflexes are probably exaggerated; there is occasional ankle-clonus; sensation, both common and special, is perfect; no loss of control over evacuations. The case belongs to a group which, though having individual differences, all possess one common feature, the spastic condition of the legs and the peculiar gait. The spastic paraplegia may exist alone, with or without affection of the arms, constituting Charcot's spasmodic tabes dorsalis, or infantile spasmodic paralysis. In two cases described by the author there were atrophic changes in the upper extremity. In addition to the present case he has seen two very similar instances. In connexion with the spasmodic paraplegia of infants other symptoms may be present, such as fits, mental defect, nystagmus, squint and inequality of pupils, deformity of chest, a symmetry of skull, delayed dentition, and defects of speech. The lesion in the case described was probably congenital, a porencephalous defect. Dr. Ross describes a very similar case, apparently due to injury in infancy. The author has never been able to satisfy himself that infantile spasmodic paralysis and congenital athetosis are dependent on injury either during or after birth. Treatment of various kinds was tried in the present case, but without benefit.—Dr. ANGEL MONRY thought that the case was interesting from many points of view. The presence of tonic and clonic spasms, with some impairment of the conduction of volitional impulses, in one and the same case, was instructive. It was suggested that tonic and clonic spasms were essentially due to differences in degree of innutrition of the nerve cells of the anterior horns, which energised the muscles. With regard to morbid anatomy, he considered that destructive lesions of any sort in any part of the pyramidal tracts could induce the symptoms of such cases.—Dr. HADDEN, in reply, said that some cases were of congenital origin, and some might be due to arrest of development of the fibres of the pyramidal tract which grew downwards from the large motor nerve cells in the cerebral cortex. In some cases the course of the cortico-medullary fibres appeared to be arrested high up in the brain; in other instances the paths were interrupted lower down. Cases had been put on record in which the spastic conditions appeared to be dependent on atrophy of the pyramidal tracts without any sclerotic change. That injury during or at birth may give rise to spasmodic paralysis seemed to have been placed beyond doubt by a case recorded by Ross. A case in which fits beginning in the paralysed arm were the first symptom was referred to; the legs were in a condition of spastic paraplegia.

Mr. JOHN R. LUNN read notes of a case of Calculus and Tumour of the Bladder. J. C——, aged thirty-five, married, a stoker by trade, was admitted into the St. Marylebone Infirmary on Sept. 8th, 1884. Four weeks before admission he noticed his water run away involuntarily, and had attended as out-patient at a hospital, where he was sounded. Two weeks before admission he was obliged to give up work and his urine became very offensive and thick. On admission, No. 10 catheter was passed, which gave the patient a good deal of pain; the urine was loaded with albumen and pus. The prostate was apparently enlarged. The patient was again sounded on Sept. 17th, when a stone was struck. Lateral lithotomy was performed on the 18th, and a large calculus removed from the bladder, weighing 1½ oz., composed of oxalates, phosphates, and a little uric acid. In addition to the calculus a new growth was felt, which was too extensive to remove. The day after the operation the patient expressed himself much better and free from pain. Vomiting set in on the third day. He passed claret-coloured urine through the wound. The left kidney was noted to be enlarged two days before he died, on Sept. 26th. At the autopsy the wound in the perineum looked very unhealthy and showed no signs of healing. The bladder weighed 8 oz., was devoid of urine, and almost the entire surface was occupied by a new growth. No secondary growths were found. Both kidneys and ureters were distended with purulent matter. The right kidney weighed 8 oz., the left 14 oz. Mr. Lunn said that he was indebted to Mr. Eve for the microscopical account of the growth. The structure of the tumour had the character of a soft cancer, the cells were rather small and spheroidal, with large nuclei, and were in no part observed to be arranged in nests. In the softer parts of the tumour they were aggregated in large diffuse, small and rounded masses in spaces formed by a scanty stroma, while in the firmer parts the stroma was abundant and fibrous, and the cells formed elongated rods and masses.—The PRESIDENT remarked on the insidious nature of disease of the bladder. The connexion between growth and calculus was not very common. He referred to a case which had been under his care of papillomata covering every part of the mucous membrane of the viscus, and to another of extensive cancerous disease. He asked if there was much bleeding during the operation in Mr. Lunn's case.—Mr. LUNN answered in the negative.

Mr. RICHARD BARWELL read a paper on three cases of Pistol Shot Wound. The first case was that of a wound self-inflicted with a Derringer of $\frac{4}{10}$th-inch bore. The bullet passed through the seventh costal cartilage, the diaphragm, the stomach, and just notching the kidney, passed out of the abdomen between the first and second lumbar transverse process. The young man survived twenty-two hours. The case was introduced partly to show the power of these small pistols, but chiefly as evidence of the very little bruising which small conical projectiles fired at short ranges produce, there being no ecchymoses round any of the openings into the viscera, &c., save a very little at the kidney. The second case was that of a gentleman who shot himself with a pistol of under ¼-in. bore. The wound was within the areola of the left nipple; but the weapon must have been held obliquely, for the bullet, missing the heart, passed through about eight inches of the left lung and lay outside the chest near the lower angle of the scapula. There was very considerable hæmorrhage from the wound, and coughing caused the blood to be driven out several feet. There was also a good deal of hæmoptysis. Strict quietude, ice, acetate of lead, and opium subdued in about fifteen hours the external hæmorrhage, but the hæmoptysis continued for six days. Pneumothorax and hæmothorax, together with surgical emphysema, were very marked. Pneumonia supervened on the seventh day. After the lapse of three weeks, during which he had been in a very precarious condition, improvement set in, which steadily progressed. On the thirty-fifth day Mr. Barwell removed the bullet, which he had hitherto avoided doing, wishing the wound of exit from the chest to become closed previously. Seven weeks after the injury the man was discharged. The third case was that of a man who shot himself in the mouth and in the ear with a revolver, ¼-inch bore. The wound first named was on the left side of the soft palate, and, penetrating that part, inflicted another in the posterior wall of the pharynx. That bullet has never been found and has given no trouble, it is probably encapsuled among the deep muscles on the left of the spine. The other bullet passed for three-quarters of an inch down the auditory meatus without injuring it on either side, then continuing its transverse course, left that channel by a small wound at its posterior part. A probe passed in here touched a substance which Mr. Barwell believed to be metallic, exactly two inches from the margin of the meatus. The depth and direction of the wound delayed any attempt at extraction, because it appeared to Mr. Barwell that the projectile must lie in very dangerous proximity to the lateral sinus. After forty-eight hours, abundance of clear serum,

which was either cerebro-spinal fluid or liquor cotunnii, became mixed with the blood discharged; the admixture of blood, then of pus, prevented any testing for sugar. The man, who was singularly apathetic, progressed favourably with the exception that a week after the infliction of the wound the parts about the angle and ascending ramus of the jaw swelled, and shortly after suppurated. On Dec. 4th there was in those parts sufficient disturbance to indicate that the projectile was producing considerable irritation, and ought, if possible, to be removed. Moreover, if, as seemed possible, the lateral sinus had been injured, the wound would in the five weeks have healed. With some difficulty, Mr. Barwell passed a Nélaton's probe sufficiently far to obtain the lead mark. Making a curved incision behind the pinna, he trephined the mastoid process to the depth of three-quarters of an inch; finding a small tract leading still deeper, he again got on Nélaton's probe the lead stain, but at a distance from the trephine hole of more than an inch. The track was cautiously enlarged with a gouge, a pair of sinus forceps passed down to the bullet, which, although very firmly fixed in the bone, was successfully removed. After this operation the man had no bad symptoms, the abscess in the jaw was opened, and the hole made by the trephine rapidly filled. All these men shot themselves, the pistols were therefore held very close, and they all used weapons the projectile of which is driven by the fulminate alone. In the last case the muzzle was on the skin, and in a medico-legal point of view it is important to note that there was no mark of burn nor of powder-tattoo. This, Mr. Barwell says, in his experience is the usual condition with weapons of that description. The other lessons from these cases are that small conical bullets discharged at short range bruise soft parts but very little, and though the projectile possesses very considerable velocity, the immediate result of such wounds, unless some peculiarly vital part be hit, is small.

Mr. MAYO ROBSON showed living specimens of two cases of Spina Bifida, which he had treated by plastic operation. Mr. J. R. LUNN showed microscopical sections of Tumour of the Bladder.

MEDICAL SOCIETY OF LONDON.

Treatment of Cervical Caries.—Necrosing Ethmoiditis and Mucous Polypi.—The Larynx in Tabes Dorsalis.

AN ordinary meeting of this Society was held last Monday, Dr. W. Miller Ord, President, in the chair. The meeting was prolonged for half an hour.

Mr. WALSHAM read a paper on the Treatment of Angular Curvature of the Spine in the Upper Dorsal and Lower Cervical Regions by a combination of jacket and collar of poroplastic felt. The apparatus was made at Mr. Walsham's suggestion by Mr. Cocking. The apparatus, which is made of one piece of felt, consists of an ordinary poroplastic felt jacket, together with accurately fitting collar and helmet piece. The jacket and collar are continuous posteriorly, the collar portion being carried upwards over the occiput, and, after encircling the neck, is bent downwards over the shoulder and upper part of the front of the chest, where it overlaps the jacket portion, and is there secured in position by straps and buckles. The cases for which it is especially adapted are those where the caries is situated too high in the spine to be benefited by a common felt or plaster jacket, and too low to be treated by the various collars in use for cervical caries; in short, for cases in which the jury mast is now so frequently used. Mr. Walsham has not been satisfied with the results of the jury mast apparatus. The plaster-of-Paris jacket has no basis of support in the small pelvis of young children, and thus the jacket did not remove pressure from the diseased vertebræ. By means of the poroplastic apparatus the pressure is removed from the bodies of the vertebræ, though the weight might be transmitted through the posterior parts of the spine—i.e., through the articular processes and their supports. The results have been very encouraging. Several of the children who could not stand before the apparatus was applied were able to walk a few weeks later. The gravest objection to which it appeared open is that it is likely to embarrass thoracic breathing; but this is an evil incidental to all forms of jacket. The further advantages of this jacket over the jury mast apparatus were that, besides that it did not slip down in young children and males, the parts are held more steady, the rotatory and lateral movements of the neck in cervical caries are controlled, there are no straps to stretch or to be in different states of tension, according to the varying positions of the head, and the patient can lie down in greater comfort. Mr. Walsham advocated long daily periods of recumbency in the treatment of this form of caries. In conclusion, he urged the advantages of felt as a material for jackets generally, as against plaster-of-Paris. Sweat did not soften the felt unless the temperature reached 150° F. The shape could be well made and maintained. He proved that felt was porous by filling a hollow ball made of felt with smoke. The smoke slowly escaped through the interstices of the felt.—Mr. W. ADAMS thought nothing could be better than the apparatus shown by Mr. Walsham, though Dr. Sayre's improved plaster-of-Paris jacket was sufficient for the treatment of all ordinary cases. The recumbent posture maintained for a long period was of the utmost value; where paralysis supervened, he advised the recumbent posture with extension of the spinal column by means of a special apparatus. Reference was made to a case under his care in which complete motor and sensory paralysis supervened somewhat suddenly. Rest on an inclined plane with extension was followed by considerable and rapid improvement of the nervous disease.—Mr. NOBLE SMITH said that the surgeon should attend to the application of the apparatus. Mr. Walsham relied not on extension, but merely on straightening the spine; in this way a sufficient amount of pressure was taken off. Paralysis might be relieved by this method of treatment. Recumbency in the prone position was most important; in a severe case in a child the prone position was spontaneously adopted.—Mr. CLUTTON referred to a form of apparatus, made of leather and iron of the same pattern as the poroplastic jacket of Mr. Walsham, which was in use at St. Thomas's Hospital. He considered that the apparatus with the jury mast was of no value. Recumbency was a most important point.—Mr. BERNARD ROTH spoke of treatment by passive extension of the spine. He asked how often ablution was performed in Mr. Walsham's patients, and what was done when caries existed high up in the neck. He had seen Fletcher's bags used with advantage.—Mr. WALSHAM said that no doubt recumbency was an invaluable mode of treatment; in disease of the first cervical vertebræ it was imperative.

Dr. WOAKES read a lengthy paper on Necrosing Ethmoiditis and Mucous Polypi. He discussed the question of the relation of the diseased bone to polypi. The disease was extensive, and began as a chronic inflammation of the muco-periosteum lining the turbinate bones as well as the cells of the ethmoid bone; this inflammation of the soft tissues was associated with necrosis of the dissepiments of bones. The catarrh spreads from without inwards. His account of the disease was drawn from a record of eighty cases which he had collected in his experience at the Throat Hospital. As to the etiology, cold in the head, an exanthem (measles or scarlet fever), and blows were the usually assigned exciting causes. Sex showed but little difference. The disease was generally bilateral, the left side was more frequently attacked than the right; it occurred at all ages after puberty, and especially in young adults of either sex. A broadening of the bridge of the nose was sometimes produced. In the first stage the thickened muco-periosteum was rather pale, and could be seen to be hypertrophied, especially over the front of the middle turbinate bone. In the proliferating stage soft reddish fleshy growths were to be seen. Necrosis was always to be detected after the first stage of the disease had been passed. In some cases the hiatus semilunaris was a good deal enlarged. A probe might be passed in many directions, and dead bone struck in the anterior and posterior ethmoidal cells. The necrosis antedates the appearance of the mucous polypi. The myxomatous tissue proliferated near the surface of the muco-periosteum, no matter whether on the free surface of the turbinate bones or within the ethmoidal cells. There was no attempt at a new formation of bone. The characters of the polypi depend partly on their situation. The bones around the nose may be implicated, and so the base of the skull may be perforated, or the orbital wall destroyed at parts, and vision may be lost. The superior maxilla may become affected, and abscess of the antrum, or polypoid degeneration of its lining membrane, take place. In the third stage of the disease thin plates of atrophied bone may be found in the midst of an exuberant polypoid excrescence. The disease, as a rule, tends steadily to progress. Mr. Edgar

Thurston had prepared many microscopical sections illustrative of the pathology of the disease. These specimens and many drawings were shown to the Fellows of the Society.—Mr. SPENCER WATSON asked whether the conclusions were taken by Dr. Woakes as applying universally to mucous polypi. It was difficult to understand that necrosis could have preceded the appearance of all polypi. He said that Professor Silvercandle had shown that one in eight individuals suffered from nasal polypi. He believed that obstruction in the nostril due to posterior rhinitis, or to deviation of the nasal septum, or to chronic hypertrophic rhinitis of the middle turbinate bone, was a frequent cause of nasal polypi.—Mr. CRESSWELL BABER thought that nasal polypi were not always preceded by necrosis or even accompanied by it. The turbinate bones vary in size in different individuals, and it might be difficult to say whether a turbinate bone was of normal size or not.—Mr. STOKER concurred with the views of Dr. Woakes.—Mr. W. PYE said that on examining the nose with a probe in cases of nasal polypi in children, he had nearly always struck dead bone.—Dr. WOAKES said, in reply, that he could not say that necrosis was invariably the precursor of nasal polypi; all he could say was that he had never examined cases of polypi without detecting necrosis. The necrotic spicules are formed *pari passu* with the development of mucous tissue. A normal middle turbinate bone was a rare structure.

The PRESIDENT and Dr. SEMON showed a case of Locomotor Ataxy, with bilateral incomplete paralysis of the abductors of the glottis openers, which they believed was more frequent than was ordinarily supposed. This stenosis of the glottis had gone on under observation, and was unaccompanied by any obvious symptoms. The larynx ought to be examined in all cases of tabes dorsalis. Charcot, McBride, and Ernest Jacob of Leeds had described similar cases of abductor paralysis. A primary rigidity of the glottis muscles was believed in by some German authorities, who said they had never seen a progressive development of the stenosis; these views were refuted by the present case. Tracheotomy might have to be resorted to ere long, and the patient had had several attacks of laryngeal obstruction, which at times threatened tracheotomy.

HARVEIAN SOCIETY OF LONDON.

Early Treatment of Concomitant Squint.—Resection of the Intestine.

A MEETING of this Society was held on the 19th ult., the President, Dr. T. Morton, in the chair.

Mr. W. ADAMS FROST read a paper on the Early Treatment of Concomitant Squint. The author submitted that in practice the truth and importance of the following propositions were not sufficiently recognised:—1. This form of squint seldom recovers spontaneously. 2. It leads, in a few months, to very great impairment of the vision of the squinting eye. 3. The majority of the cases can, in the early stages, be cured by correcting the hypermetropia with glasses. The binocular character of this form of strabismus, and the distinction between a "fixed" squint and an alternating one, were briefly illustrated by means of Mr. Priestley Smith's model. The popular notion that children squint from imitation or caprice, and that they grow out of it, was entirely erroneous. Among the cases treated at St. George's Hospital during the last four years, 60·5 per cent. presented amblyopia of the squinting eye. Amblyopia never appears while the squint is alternating. Of the cases in which there was no amblyopia in the above series, 41·6 per cent. were alternating. It commenced directly the squint became fixed. Hundreds of eyes were lost every year from neglected squint. If, when all accommodation was rendered impossible by the application of atropine, the squint disappeared, it would almost certainly cease by correcting the hypermetropia. Spectacles could be given at a very early age; Mr. Frost had often ordered them for children under four years, and had never found reason to regret having done so. When a child was too young to wear glasses, treatment might be postponed if the squint was really alternating; if it was fixed, either an operation was necessary, or the other eye must be covered to save the squinting eye from amblyopia.

Mr. FREDERICK TREVES then read a paper on Resection of the Intestine. The operation in question dated from about the year 1878, although many isolated instances had been recorded much earlier. Some 150 cases were now on record. The operation was applicable to both the small and the large intestine, and had been performed for the following conditions:—(1) Single and epitheliomatous strictures; (2) neoplasms other than cancer; (3) extensive matting of the bowels, involving obstruction; (4) irreducible intussusceptions; (5) gunshot and allied injuries of the bowel; (6) gangrenous gut in hernia; (7) fæcal fistulæ. It might also be applied to certain perforating ulcers of the intestine. The operation implied merely the application to the intestine of a simple and recognised plan of treatment which was adopted in corresponding conditions to other parts of the body. In most of the affections named, enterotomy and colotomy offered the only other means of treatment; they gave temporary relief only, leaving the cause of the disturbance untouched. In another series of cases the removal from the body as early as possible of gangrenous and putrid parts was obviously indicated. Lastly, the mortality in gunshot wounds of the bowel was so exceedingly high that the operation had in these cases great claims to consideration. The *modus operandi* was illustrated by enterectomy. There were two procedures. In one, the divided ends were united by sutures immediately after the resection; in the other the part was excised and an artificial anus established, which was closed after a time by a second operation. The abdomen having been opened, the loop to be excised was drawn out and placed upon a sponge. The gut above and below was severed either by the fingers of an assistant or by special clamps introduced by Rydygier, Bishop, Makins, and Treves. The gut was excised, and with it a triangular piece of the mesentery, the cut edges of the latter being united by a few points of suture. If the bowel was to be united, the best material was Chinese twist applied by Hagedorn's needle and needleholder. Of the various sutures, the Czerny-Lembert was the best. A row of sutures was introduced involving only the mucous membrane, and a second row involving only the peritoneum. Some fifteen points of suture were needed for the first row, and about twenty-five for the second. Of the two methods, the second was by far the better. Most of the patients were not in a condition to bear a protracted operation. Moreover, the first method did not give complete relief to the obstruction, did not ensure emptying the bowel above the obstruction, and involved great risk from fæcal extravasation owing to the distended state of the gut and to the great risk of gangrene along the suture line. Besides, there was great difficulty in uniting the much dilated upper segment to the shrunken segment below. The mortality of the operation was discussed, its simplicity urged, and a hope was expressed that its application would be cautiously and more widely extended.

EPIDEMIOLOGICAL SOCIETY OF LONDON.

Prevention of Heat Apoplexy.

AT a meeting of this Society, held on the 11th ult., Dr. Norman Chevers, President, in the chair,

Surgeon-General A. C. C. DE RENZY, C.B., read a paper entitled the Prevention of Heat Apoplexy, of which the following is an abstract:—The object of this paper was to apply Indian experience in the prevention of heat apoplexy among the troops in the Soudan. The writer resided for many years at the Multan in the Punjab, one of the hottest places in the world, and saw a great deal of heat apoplexy amongst the British troops and railway *employés*. In the month of June the temperature in the shade rises to 120° F., and a black bulb thermometer registers 176°. An ordinary thermometer, exposed in the sun's rays, registers 157°. The dryness of the air is extraordinary. The mean humidity of May is only 26°, and the maximum humidity is as low as 17°; saturation equal to 100°. Dust storms occur at very short intervals all through the hot weather. The nights are comparatively cool. In June, the hottest month, the minimum thermometer goes down to 71°. About 10 o'clock the sky becomes perfectly cloudless, and the earth radiates the heat stored up during the daytime rapidly. But there are usually three or four intensely hot nights in the year when the clouds do not disperse, and so radiation is obstructed. On such occasions the writer has found his bed so intensely hot that he had to have it sprinkled with water to make it tolerably cool. The mean daily range of May is 34·43°. The climate of the Soudan is several degrees cooler than that of Multan, and not at all so trying, and, as experience shows that a very fair standard of health can with suitable arrangements be secured for British troops at Multan, it is

reasonable to hope that, so far as high temperature is concerned, a similar result may be attained in the Soudan. Contrary to what might have been expected, Multan has long been one of the healthiest stations in Northern India. Taking the returns of the last eighteen years, it stands fifth in the order of healthiness. Bareilly stands first, with a death-rate of 12·01 per 1000. Fort William second, with a death-rate of 12·33 per 1000, while the death-rate of Multan was 15·15 per 1000, or actually lower than the death-rate of the troops stationed in England was thirty years ago. If the mortality from heat apoplexy were reduced, as it might be, Multan, notwithstanding the intense heat of its summer, would be one of the healthiest stations for British troops in the world. All through the summer of 1848 the fort of Multan was invested by British troops, who had little sickness and few casualties from heat apoplexy. Lord Gough, who was Commander-in-Chief in India at that time, was altogether opposed to the operations being carried on in the summer, as he thought it impossible that the troops could withstand the heat. The result proved that his apprehensions were unfounded. With good tents, a good commissariat, and arrangements well adapted in other respects for the protection of the health of the troops, the campaign was brought to a brilliant close by the capture of the fortress, one of the strongest in India. Heat apoplexy causes a large number of deaths among the troops; taking one year with another about 100. Heat apoplexy occurs through very different circumstances—(1) under exposure to the direct rays of the sun; (2) under exposure to great heat in the shade. The deaths under the second head are far more numerous than those under the first. For the prevention of heat apoplexy, especially under exposure to the direct rays of sun, two things are indispensable—(1) that the clothes be loose and light, so as not to interfere with the free movements of the chest and evaporation of the skin, and so as not to obstruct the cervical circulation, and (2) that a supply of drink should always be at hand to relieve the first signs of thirst. The importance of these precautions was illustrated by several striking cases that fell under the writer's notice. At the capture of Rangoon in 1852, of two sets of men who were alike in all other respects, one fought in shirt sleeves under an intensely hot sun, the other in blue cloth tightly fitting coats; many of the latter began to drop down insensible shortly after coming into action, their commanding officer being among the number. The want of water causes great loss of life from heat apoplexy on first service in India. The arrangements for the supply of water are most defective. Natives use immense quantities of water under exposure to the sun, and to this practice was attributed their immunity from heat apoplexy. While the deaths from this disease among the British troops were 20 per 10,000 of strength, they were only 2 per 10,000 among native troops. Heat apoplexy is very rare among officers, who are careful about their dress, and also to have something at hand to relieve thirst. Sportsmen who go out shooting in the hottest weather suffer very rarely. And the disease is unknown among Assam tea-planters, whose business requires them to expose themselves in the sun in the hottest season and at the hottest time of the day. The great majority of the cases of heat apoplexy among soldiers, due to exposures to great heat in the shade, occur between sunset and midnight. This was attributed to the peculiar meteorological conditions of that period of the day in conjunction with the crowding of the men in the canteen. The breeze dies away; clouds form, obstructing radiation; and while this lasts the men crowd in dense masses into the canteen, the ventilation of which is altogether inadequate for the number of men who temporarily occupy it. Crowding, even though it is only for a short period, is most dangerous when the air is very hot. The danger is much increased when, to the crowding, excess in the use of alcohol is superadded. The barracks in the evenings become as hot as ovens. As a means of cooling the barracks it was proposed that they should be douched every evening after sunset. With the present barbarous system of water-supply this suggestion would be impracticable, but if the troops are to be protected against the ravages of cholera and typhoid fever, water must be provided under pressure, as it is in more civilised countries. This proposal when made some years ago had the approval of Mr. Edwin Chadwick, but it was found impossible to give it a trial. In conclusion, it was contended that experience in the hottest parts of India warrants the hope that under good arrangements the losses from heat apoplexy among the troops in the Soudan may be kept within very moderate limits. With good tents of the Indian pattern, attention to clothing, good arrangements for the supply of water, avoidance of overcrowding, especially in tents or huts, and extreme moderation in the use of alcohol, for which tea should be substituted, the losses from apoplexy would be very small.—In the discussion which followed Sir William Smart, Drs. Murray, Scriven, Lloyd, White, Lawson, Cullimore, Comyn, and Squire, and Mr. Shirley Murphy took part.

MEDICAL OFFICERS OF HEALTH SOCIETY.

A MEETING of the above Society was held on Friday, March 20th, Dr. J. Orme Dudfield, President, in the chair.

Mr. A. WYNTER BLYTH read a paper on the Action of Disinfectants on Microzooids. The author enumerated the diseases of animals and men which may be considered beyond a doubt to have an intimate connexion with microzooids—viz., mouse and rabbit septicæmia, a fatal disease of the guinea-pig produced by the micrococcus tetragenus, the anthrax of animals and men, fowl cholera, glanders, malignant œdema, bovine and human tuberculosis, erysipelas, some forms of pneumonia, and acute osteo-myelitis. On the other hand, it had not been proved satisfactorily that diphtheria, scarlatina, relapsing fever, cholera, typhoid fever, and some others were due to microzooids, though the balance of evidence seemed to be in favour of such a view; probably zymotic diseases would come to be recognised as consisting essentially of the invasion of the tissues of individual megazooids by legions of microzooids. The term "disinfectant" the author used throughout as synonymous with "germicide." A colony of microzooids submitted to a solution of a true disinfectant, and then having been freed from the disinfectant and put into the best possible conditions for development and growth, showed no signs of life; the colony had been disinfected—that is, killed. Hence, according to this view, disinfection is either a destruction of pathogenic microzooids or a poisoning of them; the end effected being for practical purposes the same. The author then briefly detailed his own experiments on spore anthrax published in the Royal Society of Edinburgh's Transactions, and summarised the experiments of Schiff and Fischer on phthisical sputum, and those of Fischer and Proskauer on the action of chlorine and bromine. The author had made some observations on mouse septicæmia; threads were infected with mouse septicæmia and soaked for half an hour in Tuson's disinfectant, a saturated solution of sulphate of iron, a 10 per cent. alcoholic solution of cresylic acid, a 10 per cent. solution of sulphenic acid, a 10 per cent. solution of chlorozone, and a strong solution of chloride of zinc. The sulphenic acid and the alcoholic solution of cresylic acid disinfected perfectly the thread; but of the other agents some had no effect, others superficially disinfected. His most recent researches were on the pyridine bases. He had raised a pure cultivation (from the last stages of nasal catarrh) of a yellow bacillus which liquefied gelatine; the liquid gelatine then becoming yellow and fluorescent. This bacillus produced spores of moderate resistance, was not pathogenic, and grew with rapidity at ordinary temperatures. Threads infected with this yellow bacillus were soaked in a 1 per cent. solution of pyridine, collidin, lutidine, and acridine, and then, having been freed from the disinfectant, they were brought up on nutrient gelatine; the threads were found to show no signs of growth around them, whereas the "control" threads grew rapidly. The antiseptic power of pyridine was tested on the organisms found in sour milk, and pyridine was shown to inhibit growth. Since the pyridine bases are present in tobacco smoke, the smoke from an ordinary pipe of tobacco was passed through water, and the resulting solution was found to be, so far as the yellow bacillus is concerned, strongly disinfectant. The results of experiments with the yellow bacillus, when treated with solution of morphine, strychnine, atropine, and other alkaloids, were also given, from which it would seem that strong solutions will kill the bacillus. Turning to the practical aspect of the question, the author summarised the general conclusion to be drawn from these researches. Disinfectants, when they are not destructive agents, act as poisons; they poison the microzooid in a manner not essentially different from the lethal poisoning of a higher life form, and this is the reason why such

poisonous substances as corrosive sublimate, carbolic acid, and chlorine are most to be relied upon. It was evident that to perfectly disinfect, the element of lime must not be disregarded; to receive the specific excreta in a strong solution of sulphate of iron or of carbolic acid, and then within a few minutes cast the excreta into a drain, could only superficially disinfect, and such excreta might in many obvious ways again become dangerous. He considered that the best and most efficient way to disinfect a room after disease was:—First, to make it as much as possible like an hermetically sealed box, and in this box to evolve chlorine; 3 lb. of chloride of lime and 3 lb. of hydrochloric acid for every 1000 cubic feet of space. The chloride of lime was to be divided into several distinct parts in deep vessels, and to be placed as high in the room as possible; the hydrochloric acid was to be mixed with the chloride of lime gradually in the manner described by Fischer and Proskauer. The room was to be kept closed for twenty-four hours. Secondly, all things in the room capable of being submitted to a moist heat were to be taken away to a suitable apparatus. Thirdly, the floor was to be washed with a solution of corrosive sublimate (1 in 1000). The principles of this process had been carried out in the parish of Marylebone for more than a year, and the author considered the method the best at present known.—In the discussion which followed, the President, Dr. Iliff, Dr. C. E. Saunders, Mr. Kingzett, and Drs. Moore, Corner, and Willoughby took part. Mr. Wynter Blyth replied, and the meeting was adjourned.

ACADEMY OF MEDICINE IN IRELAND.

THE opening meeting of the Sub-section of Public Health was held on Feb. 5th.

The PRESIDENT (Dr. J. W. Moore) delivered an inaugural address on the Relations of the Medical Profession to the Sanitary Organisation of Ireland. He contended that the medical aspect of that organisation has signally failed, mainly from two causes—want of supervision and inadequate remuneration. The Public Health Act, 1878, gives only a permissive power (Sec. 2) to the Local Government Board to provide supervision, and naturally this power in consequence has not been exercised. Again, the remuneration allowed to medical officers of health by the various sanitary authorities under the sanction of the Local Government Board is, except in a very few instances, so shamefully inadequate that the only possible result is practically to render the Act a dead letter so far as medical inspection or advice is concerned. Accordingly, he recommended (1) that the Local Government Board, acting as the supreme sanitary authority, should divide Ireland into a suitable number of districts for purposes of sanitary inspection; (2) that each of these districts should be subject to the supervision of an inspecting medical officer of health, or, as such an officer is called in Sec. 11 of the Public Health Act, a medical superintendent officer of health; (3) that the dispensary medical officer should still act as district medical officer of health, reporting as occasion may arise, not directly to the local sanitary authority, but to the inspecting medical officer of health for his district; (4) that the Local Government Board, and not the local sanitary authorities, should appoint the inspecting medical officers of health; and (5) that these officials should be sanitary experts, independent of the local authorities, and reporting from time to time to the Local Government Board. As to remuneration, the inspecting medical officers of health should be paid, by the Treasury alone, a salary which would enable them to forego private practice, in order to devote their whole time and talents to the discharge of their very responsible and very onerous duties. The district medical officers of health should be paid, in equal shares by the Treasury and by the local authorities, a suitable salary, not a nominal one, subject to a minimal but not to a maximal scale—i.e., a salary which should not be less than a fixed amount, say one-half their salary as dispensary medical officers.—On the motion of Dr. CAMERON, seconded by the REGISTRAR-GENERAL, thanks were voted to the President for his address.

Dr. E. MACDOWEL COSGRAVE read a paper on Sewer Gas and Disease. He pointed out that in spite of the Dublin-street sewers being well ventilated, it is certain that if imperfections exist in the house-drain, sewer gas will enter, as the outer air is generally denser than that in houses and as the updraught of fires causes a strong suction. At present many houses have rubble drains, which are always imperfect, and of the pipe-drains many are defective, and hardly any houses are properly disconnected from the street sewers, dependence being placed upon water-traps, which are untrustworthy as excluders of sewer gas. The remedy is to have a properly set pipe-drain cut off from the sewer by an intercepting trap, and ventilated by openings at each end at different levels, to cause a constant current of air. Occasional flushing with a sudden forcible rush of water will render such an arrangement almost perfect. Sewer gas seems to affect health in two ways: (1) As a direct poison, causing sore-throat, diarrhœa, &c.; and (2) by devitalising the oxygen of the air, and so leading to anæmia, lassitude, depression of spirits, &c. The symptoms often show first in servants who sleep in the basement. Surgical operations and confinements are specially liable to be followed by mischief if sewer gas can find entry. The Sanitary Protection Department of the Dublin Sanitary Association affords a reliable means of examining into house drainage, and the engineer to the department (Mr. W. Kaye Parry, M.A., C.E.) states that the following grave sanitary defects were found in some of the houses he examined:—Rubble drains under house, 26 per cent.; defective pipe drains, 61 per cent.; drains not intercepted from sewers, 65 per cent.; unventilated drains, 75 per cent.; waterclosets objectionable, 83 per cent.; soil-pipe leaking, 44 per cent.; scullery dangerously trapped, 50 per cent. In many cases disease accompanied the foregoing defects, especially enteric fever, diphtheria, and illness after confinements. Medical men ought, in the interests of preventive medicine, to have drains, &c., put right before outbreaks of illness, and not wait for illness to call their attention to defective drainage.—Dr. CAMERON gave several instances of defective drainage, and said in reference to exhalations from ventilators, experiments proved there was an influx of air into drains in the morning when fires were lighted.—Dr. GRIMSHAW, registrar-general, remarked that instances came under his notice of the defective line and falls in some of the public sewers in Dublin, and the consequent difficulty in obtaining sufficient falls in house drains in some localities. There was a case where the engineer of the Sanitary Association was unable to provide a complete and efficient system of house drainage in a particular place, because the level of the street sewer was not sufficiently below the level of the floor of the basement storey of the house. In this case it was impossible to put in an intercepting trap.—Surgeon-Major HAMILTON mentioned the steps he took for the ventilation of the barrack sewers of Dublin garrison.—Dr. Doyle, Dr. Henry Kennedy, and the Chairman having taken part in the discussion, Dr. Cosgrave replied, and the Sub-section adjourned.

Reviews and Notices of Books.

Conferences on Education: International Health Exhibition. Vols. XIII., XIV., XV., and XVI.; Sections A, B, C, and D.

THE main value of the educational section of the Health Exhibition consisted in the conferences between British and foreign educationists. Much interesting information was given, and some novel views and theories were discussed. It may appear strange, however, that there should have been such a dearth of medical opinion. We think only four members of the profession spoke at all, none of them frequently.

Although most of the speakers on female education appeared to understand the importance of due attention to the physical welfare of the scholars, some of the suggestions strike us as ill-considered—e.g., the Rev. Canon Holland, who spoke of the importance of ventilation of school-rooms by raised sash frames and Tobin's tubes, had apparently become oblivious of sanitary considerations when he went on to remark: "A glass house, just large enough to hold a piano and a chair, and erected in the corner of a class-room, makes it quite feasible to have two instruments in one room. In our Baker-street school we have two glass houses in one room, and three pianos, which are all played at the same time without any collision of sound." It would be interesting to know whether the air in this school has become scientific enough to pass through the glass houses which effectually keep out sound, or whether there is some

provision for ventilating these chambers from the outside, and if so of what nature, as from their small size—about 100 cubic feet, we gather from the description—they must require a peculiarly efficient apparatus for the purpose.

We could have wished for further information from Miss Freeman as to the exact duties and powers of the female physicians whom she says all the colleges for women in America employ, and who are "salaried to keep the students well." She significantly adds that they lose their appointments if they do not do so. Can these advanced institutions have taken a leaf out of the social customs book of the "Heathen Chinee"?

The German gymnastic system was referred to by Mr. J. Holm, F.R.C.S.E., as having been productive of great good in developing "manliness." He also remarked on Ling's system, which recognises the necessity of a knowledge of anatomy in the teacher of gymnastics in order that some muscles should not receive an undue development to the detriment of other parts of the body; but that all parts should be brought equally into play, and thus equal circulation, distribution of nerve power, and nutrition should be set up. The Royal Gymnastic Institute at Stockholm requires from persons desirous of obtaining appointments (to teach gymnastics) at public schools a course of study, including lectures on anatomy, physiology, pathology, and hygiene, together with instruction in the theory and practice of gymnastics, educational, military, and medical. Physicians by a modified course can obtain a diploma enabling them to practise medical gymnastics.

Many striking instances were given of the advance in intelligence of young children under the Kindergarten system, but we should scarcely desire one of our own children to exhibit such precocity as the little boy, aged five, whose mother wrote to Mr. Fitch that he "told a builder that his mother would not take his house, and on being asked why, he replied, 'You have not disconnected your drain-pipe.' He then explained that the drain-pipe ought to be cut off with an open gully underneath."

Notwithstanding many divergencies of opinion about minor matters, it is gratifying to note the substantial agreement of most of the speakers with the views expressed by the "Lancet Commission," published in 1875, which we believe paved the way for the many reforms in school hygiene which have been established since that time.

OUR LIBRARY TABLE.

St. Thomas's Hospital Reports. New Series. Edited by Dr. S. J. SHARKEY and Mr. FRANCIS MASON. Vol. XIII. London: J. and A. Churchill. 1885.—The contents of this volume are varied, and contain many original articles, of which the following must be noticed:—Vegetable Growths as Purifiers of Sewage, by A. W. Bennett, M.A.; A Case of Osteitis Deformans, by John R. Lunn; Two Cases of General Atrophy treated by the "Weir Mitchell" Method, by Seymour J. Sharkey, M.B.; Case of Gastro-Colic Fistula, by W. Edmunds, M.D., F.R.C.S.; Cases of Tubercular Meningitis, by J. S. Bristowe, M.D.; Mediastino-Pericarditis, by H. R. Hutton, M.B.; Four Cases of Symmetrical Development of Fat, by Sir William Mac Cormac; Cases of Ulcerative Endocarditis, by R. Percy Smith, M.D. The Medical Report for 1883 has been drawn up by Dr. Hadden, and the Surgical Report by W. H. Battle, F.R.C.S.

Lewis's Practical Series: Dental Surgery for General Practitioners and Students of Medicine. By ASHLEY W. BARRETT, M.B. Lond., M.R.C.S., L.D.S. London: H. K. Lewis. 1885.—A book of this kind has long been wanted, but it can scarcely be said that this one fully supplies the want. It seems chiefly to fail in its lack of illustrations. Though the description of operations is fairly good, yet Mr. Barrett too often forgets he is addressing medical practitioners, and writes as though his readers quite understood all about excavators, chisels, and the various instruments familiar to the dental surgeon. Perhaps in future editions this defect may be remedied, but even in its present form this book will be of distinct use to those for whom it is intended, as it contains in brief and readable form, though in rather long-winded sentences, much useful and practical instruction. Mr. Barrett's views on caries are crude, but his directions as to the treatment of it are very plain, though, as already intimated, they would be much helped by a few good illustrations. One sentence in the chapter on anæsthetics cannot be too highly commended; it reads: "The undesirability of employing any anæsthetic, be it 'gas,' ether, or chloroform, without the presence and assistance of a companion, who should be a qualified medical practitioner, needs hardly to be indicated." Of course this means in addition to the operator, be he surgeon or dentist.

The Ship Captain's Medical Guide. Compiled by the late HARRY LEACH, M.R.C.P., and revised by WILLIAM SPOONER, L.R.C.P., M.R.C.S. Ninth Edition. London: Simpkin, Marshall, & Co. 1885.—This edition has been revised throughout, and whilst the general plan of the work has been maintained, extensive additions and alterations have been made. The chapter on the Prevention of Disease has been entirely rewritten, an account of some diseases not previously mentioned has been inserted, and an endeavour made to bring the treatment up to the standard of the present day. The work, which is written solely for the use of masters and mates of vessels at sea, is confined strictly to a plain and brief description of accidents and diseases that occur on board ship; and much care has been taken to show, as clearly as possible, how these accidents and diseases can be best treated by a non-professional man.

Medical Reports of the Chinese Customs Service. Compiled and arranged by Surgeon-General C. A. GORDON, M.D. London: Baillière, Tindall, and Cox. 1884.—The publication of the medical reports, an epitome of which is contained in the laborious work which we now briefly notice, was first suggested by Dr. Jamieson of Shanghai. Surgeon-General Gordon has compiled a summary of the reports. A perusal of the list of contents of the volume before us is sufficient to show how varied and extensive the subjects treated by the medical officers connected with the Imperial Maritime Service of China have been. The information relating to the state of health of foreign residents at the several treaty ports is very valuable, and will be of service to those who contemplate proceeding to that vast country. The section of the volume dealing with materia medica is a valuable collection of information regarding the general use of medicines in China. The appendix contains a vast amount of information on many subjects, and notably on the prevalence of epidemics from the earliest times; a sort of medical diary dating back from B.C. 224 has been compiled at the cost of immense labour and patience, giving a chronological record of prevailing pestilences in China, as well as of epidemics and natural phenomena, such as earthquakes, inundations, and famines, in other parts of the world.

Seasonal Map.—We have received a copy of a seasonal climatic map of the United States, graphically illustrating combined humidity statistics with isotherms, wind statistics, and seasonal tables, compiled from data of the Signal Service Bureau by Charles Denison, A.M., M.D., Professor of Diseases of the Chest and of Climatology in the Medical Department of the University of Denver. Tables for computing the comparative dryness and moisture of localities are also given. By the colour shades in which the map is printed are represented even divisions of the climate of the United States, starting from the mean for the whole country, as determined by the combined humidity statistics. The map represents a marvellous amount of labour, and cannot fail to be of great

value to meteorologists as well as to officers engaged in sanitary administrative work in the United States.

Ellis's Irish Education Directory and Scholastic Guide for 1885. Dublin: E. Ponsonby. London: Simpkin, Marshall, and Co.—This book, which is now in the fourth year of its issue, contains full information as to the Irish universities and professional schools, and the institutions in Ireland for promoting intermediate, technical, and primary education, with complete alphabetical lists of Irish colleges and schools, and copious alphabetical and classified indexes. The part of the book relating to national education has been entirely remodelled, so as to make it a complete guide to the national system. It will prove useful to all who are in need of the information it is specially designed to afford.

WE have received the second volume of the *Dictionary of National Biography*, edited by LESLIE STEPHEN. It extends from Annesley to Baird, and from every point of view is fully equal to its predecessor, which we noticed favourably in a recent issue.

Analytical Records.

THE PURE WATER COMPANY.

IN spite of modern sanitary reform, the water-supply of country places, and even of many towns, is still so unsatisfactory that the production of aerated beverages absolutely above suspicion is a matter of some difficulty as well as of great importance. In the strictest sense of the term pure water is as yet unknown to us. Even Stas, who, after chemical treatment, rectified the water used in his celebrated stoichiometrical determinations, twelve times from a platinum still, did not attain perfection. But a visit to the works of the Pure Water Company at Battersea will convince anyone that practical purity can be attained with the appliances which modern chemical and engineering science have provided. In these works water is first distilled by the powerful apparatus invented by the late Dr. Normandy, and greatly improved of late. It is extensively used in ships, and is, we understand, doing good service in the present Egyptian campaign. Nine thousand gallons a day can be obtained from the engine in the works. We analysed a sample of this water, and obtained less than half a grain per gallon of solid matter, which, as every chemist will understand, is practically nothing. This extremely pure water has, however, like all distilled water, a peculiar smoky taste. To remove this taste it is passed through an animal charcoal filter. How the animal charcoal acts is not very clear. The filtered water proved on analysis to contain about four grains and a half per gallon of solid matter, chiefly phosphate of lime. It was free from the flat and smoky taste of the distilled water, and we need not say that, dietetically, it was perfectly pure. No other water is used in the works.

Carbonic acid is prepared by a continuous process in a very large pair of Mondollot generators, made by Mr. H. Favarger of London. In this apparatus, which possesses considerable advantages over all others, the sulphuric acid is introduced by a leaden syphon, which ensures regular action and avoids all waste. The gas passes through two washers, the second of which is a glass globe in which the transmission can be watched, the aeration being afterwards effected in the usual manner. Every care has been taken to avoid the possibility of mineral or other contamination, and it is certain that no purer or more trustworthy beverage could be produced.

Considerable variety is, of course, introduced into the articles sent into the market. First, we must notice Puralis, which may be described as filtered and aerated distilled table water. Then there are the usual soda and potash waters, each of which was found by analysis to contain the proper quantity of the alkaline carbonate. More novel are the aerated quinine water, which contains in each bottle a definite quantity of the soluble sulphate, and the ginger ale, ginger punch, and ginger gin. These last are excellent preparations, which will be valuable to the army of temperance advocates, inasmuch as they are not only pleasant in themselves, but they suggest alcoholic flavour without containing alcohol.

"THE METAPHYSICS OF NATURAL HISTORY."

To the Editor of THE LANCET.

SIR,—Accept my thanks for your comments in your last issue on my lately published lecture on the above subject. That lecture is there regarded almost exclusively as an endeavour to reconcile religion and science. That such may be its tendency, I earnestly desire. But to readers of your journal, and to students generally, there is a preliminary and more immediate question. How far are we entitled to declare that there must be a certain form of energy, directivity, or determinism existing in the field of nature, which can be so tracked, step by step, from the commonest physical changes, through elementary biologic provinces into the territories of reflex action, instinct and deliberate intelligent volition, that its unity of nature is beyond dispute? That however humbly or highly developed, or differently conditioned in its modes of expression, it may be, this energy of governance is one and the same? How far must the doctrine of correlated forces be modified so as to embrace what would now be called metaphysical causation? An influence, quite outside any will of its own, determines the sex of a child before its birth. At ten years old that same biologic influence is impressing modifications upon the characters of the child through its bodily constitution; it is a boy in mind and will, because it is a boy in body; at thirty years old intelligent volition has assumed predominance; but we know well enough how deeply all is still dependent on purely biologic antecedents. Here, then, is change simply biologic eventuating in intelligent will-force without a discoverable break. And more, the original life-movement may itself be traced backwards and found rooted in physico-chemical conversion of food; and in an upward direction we go on step by step to emotions, affections, and moral cerebration. This continuity may be inexplicable, but is it not certain? Again, in my tiny book I have dared, *rubesco referens*, to assume that there may be some truth in electro-biology, absurdly so-called, and in spiritualism, equally misnamed. Where more hopefully than among the mass of your readers may one seek for assistance on this point? Can any of them produce evidence that will-force can, or will, accomplish physical results? Your friendly criticism, and that of others, has shown that these views of the subject have been inadequately brought forward in the lecture. A page or two of appendix may somewhat remedy this in a new series now preparing by Messrs. Lewis.

I am, Sir, yours obediently,

March, 1885. STEPHEN MONCKTON.

ROYAL INSTITUTION.—The following are the lecture arrangements after Easter:—Professor Gamgee: Eight lectures on Digestion and Nutrition, on Tuesdays, April 14th to June 2nd. Professor Tyndall: Five lectures on Natural Forces and Energies, on Thursdays, April 16th to May 14th. Professor Meymott Tidy: Three lectures on Poisons in relation to their Chemical Constitution and to Vital Functions, on Thursdays, May 21st, 28th, and June 4th. Mr. W. Carruthers: Four lectures on Fir Trees and their Allies in the Present and in the Past, on Saturdays, April 18th to May 9th. Professor Odling: Two lectures on Organic Septics and Antiseptics, on Saturdays, May 16th and 23rd. Rev. C. Taylor: Two lectures on a lately discovered Document, possibly of the First Century, entitled "The Teaching of the Twelve Apostles," with illustrations from the Talmud. The Friday evening meetings will be resumed on April 17th, when Professor S. P. Langley, of the Alleghany Observatory, Pennsylvania, will give a discourse on Sunlight and the Earth's Atmosphere.

THE LANCET.

LONDON: SATURDAY, APRIL 4, 1885.

THE action which has been taken by the vestry of St. Pancras, and which has led to the resignation of Mr. SHIRLEY MURPHY, brings into special prominence the unsatisfactory position in which medical officers of health are placed with regard to the sanitary authorities whom they serve. It is a fact too well known to require any further proof that in a great many instances sanitary authorities intimate to medical officers of health, either directly or indirectly, that the less they do towards the improvement of their districts, the more secure will be the posts and the emoluments they hold. And, on the other hand, the officer of health who honestly performs his duty, and makes it his first consideration to deal with all matters affecting the health of the public, quite irrespective of the private interests which are involved, often finds that his position is made so disagreeable that he is bound to resign it; or else, when the time of re-election arrives, he is thrown over and a new officer takes his place. Nothing could be more unsatisfactory than such a condition of affairs, and the time has come when all who are interested in the future sanitary welfare of the country should make it known in an unmistakable way that a change is necessary in the direction of placing the medical officer of health on a more secure footing.

When the appointment of medical officers of health became compulsory throughout the country, the Local Government Board issued certain regulations with regard to such of them as held office under their Orders; and it is quite clear, from the wording of the clauses relating to the tenure of office, that the intention of the central authority was that after a certain period of probation the election should be permanent, unless removal from office was sanctioned by the Local Government Board on the application of the authority. Indeed, the only limit to the length of appointment had reference to the first election, which was to be for a period not exceeding five years. But even as regards appointments which are made under the Board's Order, the number in which permanency has been sanctioned is very small; and, as a matter of habit, even those sanitary authorities who desire to make permanent appointments are not allowed to do so. As to those districts in which the authorities do not claim any repayment of the officer's salary from the Parliamentary grant, no guarantee whatever is required as to tenure of office, and officers of health may be appointed and dismissed as often as the authorities choose. The metropolis, owing to its exceptional legislation, is on the same footing, and any officer can be got rid of, either directly or by persecution, as soon as the authority finds that in the proper performance of his duties he is touching individual interests.

For the purposes of the Poor-law Medical Service, it was found necessary to give to the medical practitioners holding office in that service some security that they should not be dismissed without adequate reason; and though it may be that this provision has not always worked satisfactorily, yet it has enabled many officers to perform their duties fearlessly, and with the conviction that there was at least some court to which there was appeal. In the interests of public health, it is necessary that medical officers of health should be placed on a footing, to say the least, not inferior to that of Poor-law medical officers; and strong representations should be made to the Government and to individual members of Parliament with a view of securing some such end. The loss to a sanitary district of a medical officer of health who is fully acquainted with its various needs, who has shown his ability to indicate those needs and to secure their remedy, and who is sacrificed because of his very efficiency, is well-nigh irreparable; for even if his successor be as competent as he, much time must elapse before an in-coming officer can have acquired the local information necessary to the proper performance of his duties. In Mr. SHIRLEY MURPHY'S resignation St. Pancras is the principal sufferer; and the mere fact that certain members of the vestry have been allowed so to behave towards that gentleman as to compel his resignation will, it is certain, most seriously affect the future sanitary status of any man who cares hereafter to take upon himself the duties of medical officer of health in that parish. The Parliamentary Secretary to the Local Government Board has borne testimony in the House of Commons to Mr. SHIRLEY MURPHY'S conscientious and capable performance of duty; the Mansion House Council on the Dwellings of the People have publicly protested against the treatment he has received; and it is to be hoped that the publicity which has been given to this case, one out of many similar instances, will in the end lead to a change in the relations of medical officers of health to the local authorities, both in the metropolis and elsewhere. If this result be attained, those who have suffered will not have done so in vain.

THE debate on Cholera was resumed at the Royal Medical and Chirurgical Society last Tuesday, and brought to a conclusion, although an attempt was made to have it further adjourned, in order, as one speaker stated, to secure opportunity for Dr. KLEIN to reply. The rules of debate do not, however, admit of a reply except to the opener, and in the opinion of the majority the subject has for the present been sufficiently discussed. Dr. HENEAGE GIBBES denied categorically the interpretation placed by Mr. WATSON CHEYNE upon KOCH'S statement that the ileum in acute cases contains comma bacilli in pure culture; for, according to Dr. GIBBES, the small straight bacilli which he finds to predominate in such cases are specifically distinct from the curved microbe. Neither could he confirm the statement that the number of comma bacilli was in proportion to the severity of the case. Dr. HERON, who spoke later in the evening, reverted to the bacillar question, and maintained that no difference of opinion had been elicited as to the fact that KOCH'S bacillus had occurred in any other disease but Asiatic cholera; although, as Dr. THIN remarked, an impression had been conveyed that Dr. KLEIN still maintains the contrary. Dr. THEODORE ACLAND asked for information on this point, but, as Dr. GIBBES had left the room and Dr. KLEIN

was not present, no reply was forthcoming. But, assuming the truth of his interpretation, Dr. HERON pointed out the great importance of this fact as a means of diagnosis between Asiatic cholera and allied diseases, following in this the opinion long since expressed by KOCH, at whose instigation so many sanitary officers and others have been instructed at Berlin in the methods of discriminating the choleraic microbe. Sir GUYER HUNTER took occasion to reiterate his conclusion that in the Egypt epidemic the disease was not imported from India, nor did he believe that the Toulon outbreak was imported. In fact, he declared stoutly in favour of the non-contagionist doctrine, which Dr. CUNINGHAM has so persistently upheld. Yet, in the face of such facts as those furnished by Mr. MACNAMARA in his able speech, and those included in the trenchant criticism lately bestowed on Dr. CUNINGHAM'S own reports by the writer of a pamphlet entitled "On the Communicability of Cholera by Human Intercourse"—an author who is in a position to speak with authority,—it does seem astonishing that the non-contagionist doctrine should still receive so much support. Surely there is abundant evidence for regarding cholera as on the same etiological footing as typhoid fever. Mr. MACNAMARA appears in practice to have found that the most appropriate treatment is just that which KOCH finds obnoxious to the bacillus, and is therefore all the more inclined to accept the interpretation of KOCH in its most extended significance. Other speakers were less assured that the bacillus stands in causal relation to the disease. Dr. PYE-SMITH contributed some weighty remarks upon the nature of the choleraic discharge, which, from experiments made in conjunction with Dr. BRUNTON, he believes to be due to an outpouring of intestinal secretion by paralysis of mesenteric nerves in connexion with ganglia derived from the solar plexus. As might have been expected, much was said about treatment; and Dr. JOHNSON'S advocacy of elimination by means of mild purgation was attacked by many, including Sir GUYER HUNTER, Dr. JOHN MURRAY, Mr. MACNAMARA, and Dr. SCRIVEN; although the latter declared that he had found calomel most useful in the early stages. Other statements of Dr. JOHNSON were combated; but he defended his position with vigour in the short time left to him at the close of the protracted meeting.

DR. GEORGE PEABODY, Physician and Pathologist of the New York Hospital, read a paper to the Practitioners' Society on the 6th of March on toxic enteritis caused by corrosive sublimate as a surgical and obstetric application. He adduces from the records of the New York Hospital accounts of eleven cases in which the use of the perchloride as an antiseptic dressing or application was followed by obstinate diarrhœa, which did not yield to the usual remedies, which sometimes ceased on the drug being discontinued, but which in seven instances was followed by frequent bloody discharges, griping, tenesmus, prostration, and death. He was led to search out the facts by reading an article by Dr. EUGEN FRAENKEL in the February number of VIRCHOW'S *Archiv*, whose attention had been drawn to the subject by reading a short communication in the *Centralblatt f. Gynäkologie* by STADFELT of Copenhagen, in which is reported a fatal case of poisoning in a woman who was treated, after retained placenta had been removed with the hand, by the washing out of the uterus with a solution of corrosive sublimate of the strength of 1 in 1500. Four hundred cubic centimetres of this solution had been injected into the uterus, when sudden collapse occurred, from which she rallied. On the evening of the same day she had diarrhœa and tenesmus, and later, bloody stools, which continued until her death, ten days after. The autopsy showed numerous ulcers of an irregular or circular shape in the large intestine. The mucous membrane generally was congested and the ulcers frequent in the rectum. These appearances of the intestine corresponded closely with what was noticed by Dr. PEABODY in several of the autopsies he made of surgical cases where the bichloride had been used, as for irrigating abscess cavities, irrigating wound after amputation of the breast, irrigating a suprahydatid cyst; wiping the peritoneum after laparotomy for fibro-myomata with sponges wet with bichloride solution, 1 to 2000 parts. FRAENKEL says he has made autopsies of fourteen cases treated by SCHEDE with bichloride during the last two years and a half, in which toxic enteritis was produced by it. Of these fourteen cases, two, he thinks, were killed by the poison directly. In the others the drug did not seem wholly responsible for the fatal issue. Salivation is exceptional in these cases. Inflammation is always present in the large intestine, but only exceptionally in the smaller. In the large intestine FRAENKEL found very extensive superficial ulcerations, sometimes covered with loose masses of epithelium and sometimes by a torn diphtheritic membrane. The lesions of pyæmia in other organs are uniformly absent. Dr. PEABODY refers to a publication by SCHEDE of Hamburg on this subject in *Volkmann's Sammlung Klin. Vorträge*, No. 251, and also to one in the same work, No. 250, by W. THORN, assistant at the Female Clinic in Halle, which is an urgent plea for the total abolition of the corrosive from midwifery and gynæcology, alleging its great inferiority to carbolic acid, and the dangers attending its use. We think it incumbent upon us to give publicity to these publications, as we have lately recorded with much satisfaction the remarkable absence of mortality in the General Lying-in Hospital of York-road, Lambeth, where the patients are douched with solutions of the bichloride twice a day. These, of course, are only vaginal douches. We have been informed that there was, except possibly in one case, an entire absence of any indication of the constitutional action of the poison. It is clear, however, from surgical experience that this solution will have to be used very cautiously, and not less so in obstetric practice. We should be disposed to say that its intra-uterine use is not warranted. There is a growing disposition, except in extreme cases, to trust to vaginal cleansings.

THE Government Lunacy Bill is not yet printed, so that it is not possible for us to discuss its provisions in detail. So far as we can judge from the statement made by the Lord Chancellor when introducing it, the measure would seem to be one of those well meant but feeble endeavours to do right which reflect more credit on the hearts than on the heads of their projectors. Of course, it may be that in this instance the head has had more to do with the matter than the heart, and that, in point of fact, it is a concession, with ingenious reservations, made to the urgent cry for reform. We do not attempt to determine in which light the new

Lunacy Bill is to be regarded. One thing, however, is certain; an attempt must be made to improve it by amendments. In some respects this should be easy. For example, the provision by which a person consigned to an asylum is to be visited by a delegate of the Commission within a *month* (!) of his admission must obviously be so modified that the official visit shall be paid within a week as the utmost limit. If the examination and report thus made are to be of any value they must be completed at the earliest practicable date. Imprisonment of a weak-minded though not insane person for a month in an asylum would more than suffice to drive him into madness. Even three or four days of wrongful incarceration would do the utmost mischief in a great majority of instances. If the official representing the Commission, and therefore *supposed* to be impartial, does not visit within one week, it is needless to trouble to send him at all; the alleged lunatic will be quite mad before he comes! We do not complain that the Government has hesitated to abolish the private asylum system altogether with one sweep of the pen; but the Bill, as represented, trusts largely and implicitly to the energy of local reformers for its efficiency, and everything will depend on the way its provisions are carried into effect. We suspend our judgment on the details of the measure until we see it in print.

WE drew attention in our issue of March 7th last to the proceedings of the Metropolitan Asylums Board in connexion with the excessive expenditure at the Homerton Fever Hospital, and especially to the resolution which was passed by that Board to the effect that the result of the inquiry of the subcommittee showed the unfitness of the present medical superintendent for the office he holds. Dr. COLLIE has raised a protest against this resolution, and he naturally expresses surprise that it should have been passed without his having an opportunity of offering to the Board of Managers the explanations which he now tenders. The charges which, in the opinion of the managers, have reference to Dr. COLLIE arrange themselves under four heads. In the first place the general expenditure of the establishment is regarded as excessive. As to this Dr. COLLIE shows clearly that, except in so far as he has advised the carrying out of certain important and necessary improvements, such as alterations in the system of drainage, he is in no way responsible for such expenditure. The general expenditure, he declares, is controlled and directed solely by the hospital committee; and, except on rare occasions, when some special medical questions arise, the estimates are dealt with without so much as his being consulted. Another and a very important charge relates to the amount of stimulants given to patients. On no subject has there probably been a greater divergence of opinion in medical circles than on this question of the administration of alcohol in the case of the acute specific fevers, and therefore the mere citing of the amounts of wine, &c., administered per patient at different hospitals is altogether beside the mark when the point under consideration is the fitness of this or that practitioner efficiently to supervise a large fever hospital. The matter is one for medical judgment, and we are bound to say that Dr. COLLIE who has often expressed his views upon what has by some been regarded as his lavish use of alcohol, bases his practice upon what he rightly believes to be the only proper ground—namely, the welfare of the patient. Indeed, in support of his method of treatment he gives the mortality per cent. of admissions during the last twelve years in the Stockwell Fever Hospital, in the London Fever Hospital, and in the Homerton Hospital, and the result is that on a total of patients varying from 1797 in one to 3604 in another of the hospitals, the death-rates have been at Stockwell 21·54, in the London Fever Hospital 16·14, and at Homerton 15·15 per cent.

We are not now, however, concerning ourselves in any way with the question whether Dr. COLLIE's method of treatment is right, or whether sources of error may not have to be eliminated before the figures he quotes can be accepted as proving all he alleges. The point is that he honestly believes he saves life by his alcoholic treatment, and that he is able to quote statistics which he holds are in favour of his confirmed opinion. So long as this is the case it is only right that his medical judgment should be unhindered, and it is clear that on this, as also on the first head, he entirely absolves himself from the charge brought against him. A third point relates to the supply of stimulants to the staff. Some of this has been granted without any order from Dr. COLLIE, and some of it he has "years ago" declined to hold himself responsible for. There has also been some exceptional use of beer on account of the works of drainage which have been carried out. It was naturally desired to keep the men working in an infectious hospital from the neighbouring public-houses, and hence beer, as also lemonade, were provided for them. But even here Dr. COLLIE declares that he never ordered an ounce of the beverages, neither was he concerned with the quantities issued. The remaining item under this heading Dr. COLLIE regards as one coming properly within his jurisdiction. It has relation solely to the sick members of the staff, and, having regard to the heavy nature of the duties they had been called upon to perform, Dr. COLLIE declares that under similar circumstances it would be his duty to act in the same way again. Here again the matter is one essentially for the judgment of the responsible medical head. The last charge is of a different character. Excessive amounts of Beaune wine were delivered to a certain ward early in July last year. Dr. COLLIE admits that it was his duty to have checked this, and that he is properly to be held responsible for what was unquestionably a grave irregularity. But he submits that at the time in question he was engaged on many other matters for the board of managers, that the diet sheet was made up by the superintendent nurse owing to the illness of one of the medical officers, and that he is in consequence unable to offer any satisfactory explanation of the circumstance. Clearly Dr. COLLIE has erred here. But surely the past history of his services should afford ample proof that the matter is one of error alone. For a long time past the expenditure of Homerton Hospital has at intervals been considered, the cost of the establishment has been submitted to the managers fortnight by fortnight, and never during the past fourteen years has Dr. COLLIE received a hint, a caution, or a warning that his medical administration was too costly. During his long service he has received numerous proofs of the confidence of the managers in his ability as an administrator. Apart from his general work, he has been called upon to prepare land and floating hospitals against epidemics

of small-pox, special recognition of his exceptional services has been made to him, and he has all along been regarded as one of the highest authorities on the subject which he has made his particular study. Should Dr. COLLIE feel that, in the present attitude of the Managers, he can no longer hold his present post, the metropolis would lose the services of one of the most able physicians who ever set himself to cope with the control of epidemic disease by isolation; and we cannot but express a confident hope that his explanation will be accepted as sufficient, and that he will continue to hold the post for which he is so exceptionally well fitted. A Local Government Board inquiry has been ordered as regards the whole subject, and this will probably clear up all doubt as to where the fault lies.

Annotations.

"Ne quid nimis."

ROYAL COLLEGE OF PHYSICIANS.

THE Comitia on the 30th ult. was very largely attended, Sir W. Jenner presiding. The Certificate of Hygiene was awarded to Messrs. Charles Bullock, Charles W. Low, William F. Taylor, and Francis J. Tuohy, this being the first occasion of the newly established examination. A communication was read from the Treasury undertaking to comply with the request of the College to distribute free of cost amongst the medical practitioners of the United Kingdom copies of the revised "Nomenclature of Disease." A vote of thanks to the Treasury for its courtesy and liberality was proposed by Sir Risdon Bennett, seconded by the Senior Censor, Dr. Ogle, and unanimously carried. The President intimated that at the next meeting he should propose that an honorarium be voted to Dr. Ord, the Secretary of the Nomenclature Committee, for his invaluable services. The scale of payment of examiners was submitted and approved. Dr. George Johnson drew attention to the proposed publication in facsimile of the MS. notes of Harvey in the British Museum, and a committee consisting of Drs. Johnson, Sieveking, Stone, Payne, and N. Moore was appointed to report thereon to the College. Sir W. Jenner then delivered an address, in which he reviewed the various subjects that had occurred in connexion with the College during the past year. Amongst these he referred to the Medical Bill, and its withdrawal owing to the determined opposition of the Scotch universities, and stated that the measure had received the support of the College, which was more mindful of the interests of the profession and the public than of its own corporate interest. Since the Bill had not become law, the College had, in conjunction with the College of Surgeons, formed an Examining Board, which had received the sanction of the Medical Council. Objection had been taken to the fees charged for these examinations; but until the scheme was well established, it would not be possible to lower them. The question of a London medical degree was one which might well be entertained in connexion with the new board, and he thought the College might institute an inquiry into the best means for obtaining the power to grant degrees. Many other topics were dealt with, and the address concluded with a review of the careers of those Fellows who had died during the past year—an eloquent tribute, characterised by much discrimination and high-toned feeling. A cordial vote of thanks for his address was passed to Sir William Jenner, who was then re-elected President by a large majority, a certain number of votes being also recorded for Sir W. Gull, Sir H. Pitman, Dr. Owen Rees, Sir A. Clark, Dr. Quain, Dr. Wilks, and Sir Joseph Fayrer.

ENGLISH VITAL STATISTICS IN 1884.

THE Registrar-General's Abstract of Marriages, Births, and Deaths, registered in England and Wales during 1884, has just been issued as a Parliamentary Return. The marriages were fewer than those recorded either in 1882 or 1883, and were equal to a rate of 15·1 persons married per 1000 of the estimated population. This marriage-rate was as low as that in 1881, and very slightly above the low rates in 1879 and 1880, when the present depression in the marriage-rate was most marked. In sympathy with the long continued depression of the marriage-rate, the birth-rate is also much depressed, and did not exceed 33·5 per 1000 last year and showed but a slight recovery from the exceptionally low rate in 1883; it was 1·4 below the mean rate in the ten years 1874-83. The deaths registered last year were equal to a rate of 19·6 per 1000, and was almost identical with the rates in the preceding two years, 1882 and 1883, which were 19·6 and 19·5. The mean annual death-rate in the first four years of the current decennium was but 19·4 per 1000, and was no less than 2·0 below the mean rate in the ten years 1871-80, in the latter half of which period a considerable decline in the national death-rate had already set in. The marked decline in the death-rate of the last four years signifies that nearly 213,000 persons in England and Wales survived those four years whose deaths would have been recorded had the death-rate equalled the mean rate that prevailed during the preceding ten years. The natural increase of the population of England and Wales last year by excess of births over deaths was 376,623, and was higher than in any previous year on record, except 1881, when the death-rate was unprecedentedly low. On the other hand, 150,652 English emigrants left the United Kingdom during the year (fewer by 19 per cent. than those in the previous year), whereas the number of immigrants and of returned emigrants is unknown. The net increase to the population of the country cannot therefore be ascertained. From a health point of view the vital statistics of 1884 were eminently satisfactory, and the continued depression in the low marriage-rate, viewed as the reflex of the commercial depression, was to some extent counterbalanced by the decline both of emigration and of pauperism.

ALLEGED DEATH FROM VACCINATION.

ON Saturday, March 28th, Dr. Danford Thomas, the coroner for Central Middlesex, held an inquiry into the cause of death of a child named Walker, aged three months. From the evidence it appears that deceased was vaccinated by Mr. Claremont, public vaccinator to the St. Pancras district, on March 5th. At that time it seemed quite healthy. On the 12th—the day being very cold—it was taken for inspection. Two days afterwards the mother called in Mr. Whitefoord of Albany-street, and that gentleman diagnosed "congestion of the lungs and brain." Death took place from convulsions on the 22nd ult. Mr. Whitefoord signed a certificate to the effect that the fatal issue was due to vaccination, blood poisoning, and convulsions. Upon the information laid before him the coroner very wisely determined to hold an inquest. The post-mortem examination was performed by Mr. Pepper, in the presence of the gentleman named above, Mr. Sweeting of the Local Government Board, and other members of the profession. The vaccination marks were perfectly normal, there being not the least trace of ulceration beyond the adherent scabs. The surrounding areolar tissue and the axillary lymphatics showed no trace of suppuration. The internal organs, with the exception of the lungs and brain, were free from disease. There was no sign of acute fatty softening or other result of septic intoxication or infection, no thrombosis or hæmorrhagic infarction. There was no effusion into the joints. The lungs showed

acute capillary bronchitis, and patches of collapse consequent on the obstruction to the passage of air from the blocking of the tubes. There was no pneumonic consolidation. The pia mater was infiltrated with puro-lymph; the middle ear was healthy; no evidence of tuberculosis was discovered in any part of the body. On being questioned by the coroner and jury, Mr. Pepper stated that in his opinion vaccination had no other part in causing the death than that for the time being it somewhat depressed the vital powers, and so rendered the tissues more vulnerable; and, further, that the capillary bronchitis and pia-meningitis were in all probability directly due to exposure to cold. With regard to the latter lesion, he deposed that inflammation of the cerebral meninges was not uncommon in young children apart from vaccination or any other discoverable source of local irritation. Mr. Sweeting testified to his having examined the vaccinifer—a perfectly healthy child exhibited in court,—its vaccinifer, and about thirty other children vaccinated from them, and that in only one case had the arm assumed unhealthy action, and that as the result of an attack of measles contracted four days after vaccination. By Mr. Whitefoord's certificate, it would seem that he intended to convey that vaccination had in some way led to septic poisoning, and so to the death of the deceased; but when submitted to interrogation, Mr. Whitefoord had no hesitation in saying that by "blood poisoning" he meant only the ordinary effects of arm-to-arm vaccination, which he considered an undesirable method of procedure. To our minds the public and the profession generally would be led to draw a very different conclusion from the terms of that certificate, and the jury by their verdict recorded their sense of disapproval of Mr. Whitefoord's nomenclature when they found his certificate "misleading and incorrect." We do not think that Mr. Whitefoord can claim to represent the opinion of his professional brethren in considering that the "congestion of the lungs" was due to blood poisoning, and not to exposure to cold, on the grounds that the appetite of the patient was not completely lost, and that there was no difficulty in breathing. The latter statement of fact, however, was directly traversed by the mother of deceased, for she avowed that one reason why she sought medical advice was on account of the difficulty of breathing which Mr. Whitefoord failed to recognise. As regards arm-to-arm vaccination, it is only necessary to add that the Local Government Board have issued instructions that it is preferable to vaccination by ivory points. The wisdom of such instruction seems plain enough. The virus when exposed has a chance of undergoing decomposition, which, although it may attenuate the specific principle, opens up the possibility of introduction of septic matter. Besides, it has been proved by experiment that it is impossible to remove the whole of the virus from the points, as some of it passes into the pores of the ivory. We cannot help expressing our conviction that Mr. Whitefoord should have more carefully weighed the probabilities as to the construction likely to be placed on the wording of his certificate. The cause of vaccination has enough to contend against without its opponents being furnished with phraseology which does not convey a complete representation of facts, and, as in this case it seems, not even a correct statement of opinion.

ATHETOSIS BEFORE AND AFTER HEMIPLEGIA.

THE relations of convulsion to paralysis form one of the most interesting chapters in the pathology of the nervous system. The popular mind sees a wonderful contrast between convulsion and paralysis, and with good reason. Yet there are many considerations which tend to diminish the contrast. The causes which give rise to involuntary movements need only to be intensified in order that paralysis may result. A moderate defect in the nutrition of nervous tissues subserving motor functions may be outwardly expressed as epilepsy, chorea, or some other form of involuntary movement; whilst a more marked defect in the nutrition would be followed by paralysis. It is true that in many instances genuine irritation calls forth some form of tonic or clonic spasm, which may end in paralysis from exhaustion consequent on the excessive irritation. Perhaps the majority of cases of Jacksonian epilepsy which are followed by paresis may be thus explained, though it is highly probable that a condition equivalent to irritation may be set up as the result of a mere loss of nutrition. Paralysis which is not caused too rapidly is generally preceded by some form of spontaneous movement. At a recent meeting of the Société de Médecine et de Chirurgie of Bordeaux, M. Durand related the case of a man aged sixty-nine who was one day seized with severe epistaxis. The next day a tremor exactly similar to that seen in cases of post-hemiplegic athetosis was observed in the left arm and leg; at least so states the report from which we gather this account. There was no loss of consciousness. A day later the convulsions were replaced by hemiplegia. On the following day the movements had returned, and hemianæsthesia was detected in the convulsed members. The further history of the case was not related, and the description given of the movements is inadequate for a proper recognition of their nature; nevertheless the case is an interesting one.

THE MORTALITY OF PIT VILLAGES.

THE report of Dr. Brown, the medical officer of health of the Winlaton Rural District and of the Blaydon and Pyton Union Districts, has been kindly forwarded to us. It should be widely circulated in the district of Newcastle, as throwing much light on the causes of death that obtain still in villages and small communities in the very heart of the district which is associated with all that is effective in engineering and mechanics. If a little of the genius that has been so lavishly spent on the means of locomotion could only be spared for increasing the means of life, or rather abating the causes of death, what great results would accrue. How much healthier the children would be, and how much happier the parents. Life itself would be ever so much more worth living if the diseases by which it is blighted and impoverished from infancy upwards could be curtailed or abolished. If untainted water could be supplied and the house space increased, infantile diarrhœa and typhoid would largely disappear, and the insidiously introduced infection might have some chance of isolation. If the Blaydon Sanitary Authority is disposed to effect these beneficent changes, it need do no more than read Dr. Brown's report and act upon its suggestions. The significance of much of the disease of which he speaks is unmistakable. Twenty-one deaths in a population of 11,800 from summer diarrhœa; 45 deaths, *in the third quarter of the year*, under five years of age, in a total of 77 deaths; 14 deaths from enteric fever at Blackhall Mill; 68 victims to lung disease, being nearly one-fourth of the whole number of deaths, and 60 deaths of infants: from thrush, 8; tabes, 10; meningitis, 12; convulsions, 18; and premature birth, 12—convey to the medical mind conditions of existence which not only kill, but which debilitate and impoverish those who survive. The mortality of the whole district is that of a crowded city rather than that of rural villages. We will not here reproduce Dr. Brown's account of the water-supply and its intimate relation with wells and ashpits and privies. His language is not that of a sensational alarmist, but of an earnest and kindly physician; and we cannot but hope that it will have the attention of his sanitary authority; and let us hope, also, of beneficent ladies of the district, who, with

a little pains, might diffuse among the people intelligent ideas of food, fresh air, housekeeping, &c., pending the arrival of that period described by Dr. Brown when the School Board authorities will think it a fundamental part of their duty to instil into the juvenile minds under their care elementary ideas of health and its conditions.

SUCCESSFUL NEPHRECTOMY AND NEPHROTOMY.

A MAN, aged twenty-seven, has just left the Queen's Hospital, Birmingham, in capital health after removal of his greatly enlarged right kidney by Mr. Jordan Lloyd. The patient had suffered periodically from attacks of right nephralgia for nineteen years, and several experienced practitioners had diagnosed renal calculus. On Nov. 18th, 1884, the kidney was exposed through the loin, its substance incised, and its cavity explored with the finger. The kidney was found enlarged, dilated, and pouched, but without stone. Twelve days later the patient had an attack of nephralgia, followed by a kind of pyæmia. The wound at this time had nearly healed. The general health had so far improved that on Feb. 8th Mr. Jordan Lloyd excised the kidney, through a wound made in the old cicatrix. The gland proved to be greatly enlarged, but its substance was thinned and dilated, without stone. The kidney measured eight inches in length, and the pelvis twelve inches in circumference. The patient rallied quickly, made a rapid recovery, and was discharged on March 19th, with a small discharging sinus in his loin, but otherwise, to all appearance, in perfect health. *La Gazzetta degli Ospitali* reports that on March 8th Professor Vincenzo Daffilo performed nephrotomy at the Ospedale degli Incurabili at Naples for suppurative nephrosis. The walls of the cyst, about three-quarters of an inch in thickness, were closely adherent to the lumbar muscles, the peritoneum, and the diaphragm. The edges of the wound in the skin and cyst were united by points of interrupted suture. The cyst, which had previously been evacuated eight times with Potin's aspirator (yielding a pint and three-quarters of purulent liquid each time), was again emptied in the same way on March 8th. The free extremity of the twelfth rib was resected at the same time. The operation was completed under ether in forty minutes, with the strictest Listerian antiseptic precautions. The temperature has not exceeded 38° C., and the patient is making excellent progress towards recovery.

MALE NURSES FOR MEN.

THERE is some reason in a suggestion which has lately come under our notice, that greater facilities than exist at present should be afforded to steady and intelligent men who are willing to devote themselves to nursing the sick of their own sex. That some such nurses are to be found is not denied. Among others, we may mention the male attendants on lunatic patients—men skilled in the management of a special and very trying form of disease; then there are the "watchers," who belong to the Jewish community, and combine the office of a nurse with certain religious functions. Still, the suggestion we have referred to indicates a want in our system of treatment. It would be easy to enumerate cases in which the services of men would be preferable to those of women in a sick room. In old age, for example, when prostatic and vesical troubles are apt to show themselves in men, or at any age for the after-care of operations in the same region, one may, without excessive refinement of feeling, choose that the necessary manipulations should be performed by the male hand when that has by training become endowed with feminine tenderness. It must, of course, be admitted that true delicacy of feeling is quite compatible with every necessary work, and particularly with one so humane as that of attendance on illness; but there seems no reason why an invalid should not be able to satisfy his own wish in the matter. Another and more pressing argument in favour of male nursing is founded on the greater physical strength and endurance of men as compared with women. Many non-professional persons have witnessed the real advantage conferred by muscular strength—in dealing, for example, with paralysed patients. To lift a heavy man bodily is no trifling task even for the strong. In some cases it is frequently necessary; and it seems somewhat unfair to expect that women of exceptional strength should always be available for such an emergency, or that the aid of another woman or a male relative of the invalid should be conveniently near to make up any deficiency, when many men, if trained, could satisfy every requirement single-handed. Some of the general hospitals would, therefore, we think, do well to assist the formation of a nursing staff of men by using for this purpose the means of teaching which their wards so amply afford. Recent experience has proved that if the course of education could be made to include ambulance work, a reserve force of assistants might be formed whose services would be of great value to the military authorities in case of war.

HORSEFLESH AS FOOD IN MANCHESTER.

THE question as to how far the consumption of the flesh of diseased animals may be carried without injury is one which cannot yet be answered with exactness. Probably it never will be. It is obvious notwithstanding that such meat can never be relied upon to furnish the same nutriment as that of a sound and well-fed animal; and again, that so long as the muscular tissues are traversed by the same organic fluids as the seats of disease, especially if the latter be contagious, they cannot be eaten without risk. A partial security is afforded no doubt by bleeding the carcase efficiently, by using as food only the muscular tissues, and by thorough cooking. None of these, however, can do more than mitigate the probable ill-effects of such haphazard feeding, and the danger thus incurred is proportionately enhanced by the fact that many of the poor upon whom such fare is apt to be foisted content themselves with eating the liver and other viscera, which are particularly apt to suffer from infectious processes within the body. These considerations will help us to understand what is, or at least may be, implied in a statement recently published that horseflesh is being sold in large quantities to the poorer inhabitants of Manchester, under the name of beefsteak, and, further, that many of the slaughtered horses were believed to be diseased. The Local Government Board have properly taken the matter in hand, and will, we hope, succeed in excluding from the market of a prosperous English city a form of food which even in its healthy state is not looked upon with favour as a staple of our national produce.

ALBUMINURIA IN CATS.

THERE frequently exists in the kidney of the cat an enormous accumulation of fat in the cells of the parenchyma. The question has been debated whether this fatty degeneration is pathological or physiological. M. Mathis believes the condition to be abnormal, though of frequent occurrence in cats. The disease is of a different order from that of ordinary Bright's disease; it is not the result of an inflammation, but is due to excessive storing up of the fat—a function which appears to be normal for the kidney of the cat, just as the subcutaneous and subperitoneal tissues are the usual magazines for the storage of fat in other animals. Excessive accumulation in the kidney leads to interference with the function of secreting or excreting urea, and it diminishes the power of taking up the albumen thrown out from the blood in Bowman's capsule. The result appears to be the same as in ordinary Bright's disease, "if we except," says M. Mathis,

"the disorders due to increased blood-pressure." A want of docility, with capricious temper, is believed to be the chief clinical symptoms of the disease in cats, and, according to our author, albuminuria is always found under these circumstances. An account of this steatosis of the kidney may be read in the *Lyon Médical* of March 15th.

THE ROYAL NATIONAL HOSPITAL FOR CONSUMPTION, VENTNOR.

THE Sixteenth Annual Report of this Hospital shows that it is what its name implies, a National one. Of the 6163 patients who have been received into the hospital, about half have come from London and Middlesex. The other half have come from nearly all the counties of England, from Wales, from Ireland Scotland, and the Channel Islands. During the last year no less than 608 patients have been under treatment. But new blocks of buildings, chiefly at the expense of an anonymous friend, are to be opened in the present year, and another block of buildings, to commemorate the generosity of the late Mr. John Jones, is in course of erection. In view of the great importance of the work of the hospital and its imminent extension, it is highly important that the staff of local physicians should be increased. We made this suggestion in a former year, and we make it still more urgently now. It cannot be better carried out than by appointing Dr. Whitehead and Dr. James M. Williamson, who are already Honorary Surgeons, to Physicianships. It is no secret that Dr. Williamson has applied to the board of management to be transferred from the surgical to the medical staff. He states that surgically there is no demand for his services in the hospital, while medically there is a large field for them. His connexion with the hospital, first as resident physician, and then as surgeon, dates as far back as 1873. We should regard his appointment and that of Dr. Whitehead to the Physicianship as not only just to them, but as likely to be advantageous to the hospital. The case of phthisical patients is one demanding much care and time, and these cannot be given with the present staff.

SANITATION AT LEEDS.

THE sanitary supervision of so vast a town as Leeds presents unusual difficulties. A rapidly increasing population, estimated at 327,324, is spread over 22,974 acres of hilly ground, which it has been found necessary to divide into thirteen sanitary districts. A special sanitary inspector watches over each district, and these thirteen inspectors contrived in the course of twelve months to visit 17,011 houses. Considering that 6746 of these houses required sanitary improvement, it will be seen that the inspectors have been greatly overworked. Some of the cases were particularly instructive and significant. Thus, of 3943 houses with defective drainage, zymotic disease occurred in 323 before the evil could be remedied. In one house, to all appearance perfectly drained, there had been case after case of scarlet fever; ultimately it was found that the soil-pipe leaked. In another house, where diphtheria had occurred, a hole was discovered just below the trap of a drain; and this was especially remarkable, as the tenant had recently removed into this house on account of having lost her husband from blood-poisoning due to the defective drainage of her previous dwelling. In the northern district, the family of a small provision shop keeper were attacked by diphtheria. There were four cases in all; the mother and a child died, and the business was almost ruined. Dr. G. Goldie, the medical officer of the borough, has very properly published a coloured illustration of the drains of this house. In four different places the earthenware pipes passing under the house had been chipped; but in order that a two-foot run of piping might not be lost the broken side had been turned upwards. In this way leakage of water might be avoided, but sewer gas could freely escape into the house. Fortunately such trifling with human life could not now be repeated in Leeds. In June, 1878, the present building bye-laws came into force. According to these regulations, all drains must if practicable be carried outside the houses. When this is not possible, they must be laid in concrete and cemented. These works must further be tested and examined by the municipal officers, who insist on their being truly and properly laid, trapped, and ventilated. But if the bye-laws offer some guarantee for new houses, the old houses can only be remedied by the energy of the sanitary inspectors who, we reiterate, are much overworked.

TABETIC LARYNGEAL CRISES.

AT the last meeting of the Medical Society, Dr. W. M. Ord showed a patient the subject of tabes dorsalis, and Dr. F. Semon demonstrated the presence of incomplete bilateral paralysis of the abductors of the vocal cords in this patient. It appears that the stenosis of the glottis has developed and steadily increased during the past three months, whilst the patient has been under observation. The patient at first did not admit that he had suffered in any way from symptoms referable to the larynx; but later on, however, he experienced severe attacks of choking, which at times seemed to call for tracheotomy. Some authorities regard the laryngeal disturbance as being due to a primary contracture of the muscles of the glottis, but the case in question would seem to lend support to Dr. Semon's view of a slowly advancing paralysis of the openers of the glottis. Dr. Ord is in the habit of examining laryngoscopically all cases of nervous disease, and especially of tabes dorsalis, and there can be no doubt of the value of a systematic examination of such cases. For a history of laryngeal trouble may not be obtained, indeed no laryngeal disturbance need ever have occurred, and yet the laryngeal muscles may be obviously affected.

VEGETABLE FOOD FOR CHILDREN.

MR. SAMUEL MORLEY, with his usual public spirit, has been trying to help the cause of temperance and of thrift by a side-stroke in the direction of dietetics. At a vegetarian dinner given by him on Saturday to the villagers of Leigh, he advanced several reasons why this form of food should be more generally appreciated than it is. He referred to a statement that thorough-going vegetarians are usually total abstainers, advised that children should be largely fed on vegetable fare, and advocated the more extensive cultivation of herbs and fruits as being an industry available for very many of the labouring classes, and less tried by competition than that of cereals. Much might be said on each of these heads. Probably the strictest vegetarians are non-drinkers; but this rule is of course not absolute, and temperance, where it prevails, is no doubt partly a virtue of necessity or of inclination, or a principle, and does not arise out of abstinence from meat. In illustration, one might profitably compare the sober and herbivorous peoples of the tropics and subtropic zone with the largely, though not wholly, grain-eating inhabitants of Northern Scotland, whose sobriety is certainly not above question. The most valuable suggestion, however, in this well-timed address is, it seems to us, that which applies to the food of children. The body of the child consists in great measure of fluid and fatty components, and in a comparatively moderate degree of the active muscular tissues. Its income of nourishment, again, goes rather more to the building up of its constituents than to the supply of their functional

expenditure. The more inert materials, such as those of bread, are consequently in request for the laying on of substance; the more energising, as those of meat, find proportionally less occupation. We are not vegetarians, and we think Mr. Morley is not strictly such; but we probably agree in this, that for some persons, and especially children, much can be done in feeding with little meat. It is to be noted, also, that a child's food must be abundant in order to fulfil its purpose. How much more easily he may have plenty to eat of vegetable than of mixed or meat diet in the poorer ranks of our countrymen is too obvious to need remark.

THE HEALTH OF OUR TROOPS IN THE SOUDAN.

So far as we have information on the subject, the health of the troops employed in the Soudan has been remarkably good, and the arrangements made by the medical staff for the prevention, so far as possible, of disease, for its treatment when it occurs, and for affording aid to the wounded, have been most successful; indeed, they are described by the special correspondents as "admirable." But we must not lose sight of the fact that a period is now coming on when the resources of the medical service will be very severely tested. The enforced inaction of the troops during the hot season must undoubtedly prove very injurious; and the effects of solar influence on the men who must necessarily be exposed to it cannot fail to tell on the sick-list. This is indeed already beginning to be manifest at Suakim, where during the late operations several cases of sunstroke occurred. We may look for a somewhat heavy list of such cases, and of heat-fever, dysentery, and possibly cholera. A number of cases of enteric fever are already stated to have been admitted to hospital, and there seems too good reason to believe that they will increase as the season advances. It is satisfactory to know that every provision has been made which foresight could dictate; that there is abundance of medical comforts at hand; that adequate arrangements have been made for the careful nursing of the sick; that an ample supply of ice is to be had as required, and that the means of transport in hospital ships fitted up with every appliance for the treatment of the patients and the efficiency of the medical service have been provided on a very liberal scale. We have not the least doubt that everything will be done by the heads of the medical service which practical experience and scientific knowledge can suggest, but we cannot help feeling anxious about the health of the troops during the coming hot season.

SALIVARY CALCULUS IN A MEDICAL MAN.

DR. DE RATO Y ROCES describes in the *Revista Asturiana de Ciencias Médicas* his own case of salivary calculus. When a child the sublingual glands were indurated and painful; afterwards that on the right side disappeared, but the left gland continued to cause trouble, the pain being felt in Wharton's duct, and there being increased secretion of viscid saliva. These symptoms, however, disappeared for a time. For several years, especially during the later months, pain and inflammation have returned, sometimes extending to the right side. After the acute symptoms have subsided a permanent induration has always remained. Last December Dr. de Rato suffered from a more severe attack of this kind than usual, accompanied by repeated rigors, followed by severe pain and febrile disturbance. Afterwards the inflammation extended, and glossitis and amygdalitis prevented speech and the ingestion of food; then came a copious secretion of viscid saliva. By the fifth day, when the inflammation had to some extent subsided, a probe passed into Wharton's duct detected a calculus, which was extracted by forceps the following day. It was of the shape of a date stone, weighed 540 milligrammes (8·37 gr.), and of the hardness of chalk. Externally it was of a dirty white colour with reddish spots, and internally it was white. Since the extraction of the calculus the induration remains, and Dr. de Rato believes there are also small calculi in the duct.

BIRMINGHAM MEDICAL INSTITUTE.

DR. THOMAS UNDERHILL, J.P., presided at the annual meeting of the Birmingham Medical Institute on the 26th ult. The number of members is now 204, and during the past year no less than 597 books have been added to the library, which now consists of 9274 volumes. The annual income is not yet quite equal to the expenditure, but as the building and library are free from debt, the endowment unencumbered, and the number of members steadily on the increase, a growing feeling of confidence pervaded the meeting. Special votes of thanks were passed to the president, the honorary librarians and secretaries, and very important additions made to the committee by the election upon it of Mr. T. F. Chavasse, Mr. Jordan Lloyd, and Mr. Bennett May. One special feature of the Birmingham Medical Institute is that no ballot or other form of election is required to place a registered medical practitioner on the roll of members. The only requisite condition is that he undertake to observe the regulations, and be recommended by six members of the institute, of whom three shall be members of the managing committee. When this very open method was substituted for the ballot previously in force, it was feared by some that undesirable results might ensue; but in practice it has been found that the six signatures required to constitute membership afford all requisite guarantees. For the ensuing year, Mr. Sampson Gamgee was elected president of the institute, and Dr. Rickards and Mr. John Greene vice-presidents. The honorary librarians, Mr. Lloyd Owen and Dr. Saundby, and the honorary secretaries, Mr. W. G. Archer and Mr. Joseph Hunt, were re-elected.

PHARMACY IN BUENOS AYRES.

A REPORT has been made by Señor Puiggari to the National Department of Hygiene of the Argentine Republic concerning the state of pharmacy in Buenos Ayres. By means of a legalised system of granting royalties for pharmacies to non-resident proprietors, and by the permission given to medical students of whatever standing to take the title of pharmacist, a number of those establishments at present in the city are practically in the hands of very incompetent persons. In many of them Señor Puiggari found no measures, and in some where such articles existed the person in charge was incompetent to make use of them. The same remarks also apply to reagents. The examination of the drugs, too, pointed to lamentable ignorance or carelessness on the part of many of the compounders. Taking a simple and cheap substance, acid. sulph. dil., which, according to the Codex, should contain 10 per cent. of sulphuric acid, the proportions in a number of samples taken varied between 5 and 23 per cent. Again, liquor arsenicalis, which should contain 1 per cent. of arsenious acid, was found to vary from ·06 to 1·57 per cent. Coming now to an expensive drug, opium, samples which ought to have contained 10, or at most to have varied from 8 to 12, centigrammes of morphia, actually varied from 8 milligrammes to 18 centigrammes, those containing a serious deficiency being much the most numerous. In order to remedy this condition of things Señor Puiggari recommends the abolition of the royalty system, the separation of the faculties of medicine and pharmacy, and that no one should be granted a licence for a pharmacy without the production of his diplomas and other certificates. He points out, also, the extreme facility with which the pharma-

ceutical diploma is granted in the Medical Faculty of Cordova. The President, having considered this report, states that it is impossible to veto the royalty system, but orders that the names of all pharmacies of that kind be published twice a year, so that the public may have the means of judging whether an establishment is or is not under competent management.

A COUNTY COURT JUDGE ON THE REMUNERATION OF MEDICAL MEN.

AT the Framlingham County Court lately, before his Honour, Judge Sir Francis Roxburgh, Q.C., Mr. Alexander Harkness, Surgeon, Debenham, sued Mr. Oscar W. Roberts, of the Club, Malvern, for attendance on Mrs. Roberts. The charges were, roughly, at the rate of 7*s.* 6*d.* per visit and 2*s.* 6*d.* for medicine. The visits often occupied from three quarters of an hour to an hour. The distance from the patient's house was two miles, and the defendant was in good circumstances. In spite of some medical evidence on the defendant's side, alleging the excessiveness of the fees, the judge allowed them, and remarked that he did not know a class of men who were paid worse than doctors in the country. He considered the charges were quite reasonable. We refer to this judgment with the more pleasure that it is only one of several recent decisions by county court judges in which the charges of medical men have been upheld. Medical men are, perhaps, a little too slow to assert their legal claims against ungrateful patients.

HOSPITAL SATURDAY FUND WEEKLY CONTRIBUTIONS.

AMONGST various papers sent us by the Hospital Saturday Fund is a sheet which may be used for *weekly* contributions in every week from March 21st to September 5th, the day of the collection. We have always felt that this was the direction in which the Fund can, and ought to, be developed; and we heartily rejoice to commend it to the favourable notice of foremen and others in a position to promote the Saturday collection, which has certainly never reached a figure worthy of the working classes of the metropolis.

THE AMERICAN MISSION IN SYRIA.

WE have been favoured with the statistics of the American Presbyterian Mission in Syria, including the medical work at St. John's Hospital. The physicians of the Medical Department of the Syrian Protestant College are appointed by the Order of St. John in Berlin as the medical attendants of the "Johanniter Hospital" in Beirut. This charity is supported by the Order of St. John, and served also by the Deaconesses of Kaiserswerth. In 1884 there were 571 in-door patients and 7489 treated in the Polyclinique. No part of the work of the mission does more to justify the eulogy of Lord Beaconsfield—"those sublime men, the American missionaries"—than the medical and surgical part.

THE POISONS BILL.

THE new Poisons Bill, recently introduced into the House of Lords, appears to have excited general dissatisfaction. At a special meeting of the Chemists and Druggists' Association, held at Birmingham last week, and attended by representatives of 4000 chemists, the measure was strongly opposed, as being inimical to the interests of those most intimately concerned. A strongly-worded resolution was carried by acclamation pledging the meeting and the Association to oppose the Bill by all constitutional means, and a special fund was opened for the furtherance of this object. It is stated officially that the Privy Council Office have had the Bill under discussion for some considerable time, and that the schedule has been the subject of prolonged deliberation. It is to be regretted that greater success has not attended these efforts.

THE ROYAL NATIONAL LIFEBOAT INSTITUTION.

IF medicine in its ancient and more homely sphere restrains and seeks to foil the efforts of disease, it cannot in its wider and public application remain unsympathetic towards all other motives and means by which its charge of human life is profited or saved. There are certain points in which the spirit of the National Lifeboat Association is in striking concord with the genius of our own profession. Each has to recognise and contend with an unseen extra-human influence of storm or illness, to read and forecast its peculiar symbolism, to guide a system of preventive skill designed to save life, and to heal or to rescue that life in accordance with laws of a written science. Both meet on common ground when measures of resuscitation must be used in order to complete the work of deliverance from the power of the sea. As medical men, therefore, we are gratified to learn that the sister service of recovery continues her work with unabated vigour, and we do not doubt that every member of our faculty will render her that help which need and opportunity may direct.

THE SICK AND WOUNDED AT SUAKIM.

OUR special correspondent at Suakim, in a telegram dated March 27th, states that the wounded have been removed to the hospital ship *Ganges;* the beds are all occupied but three; no deaths had occurred on board. Captain Dalrymple received a gunshot wound over the clavicle, through the spine of the scapula. The splinters of bone and the ball were removed, and he is doing well. Lieutenant the Hon. A. D. Charteris received a spear wound of the palm of the hand. The hæmorrhage was stopped without difficulty, and his condition is favourable. Surgeon Duigan, R.N., had a bullet wound through the scapula and forearm. He is progressing very satisfactorily towards recovery.

POISONING BY ILLUMINATING GAS.

DR. BIEFEL and Dr. Poleck have recently discussed in the *Zeitschrift für Biologie* the question of the relative fatal effects of charcoal fumes and of illuminating gas, it being asserted that in the former case ·19 per cent. in the air of CO destroys human life in thirty-five minutes, while a limit of 1 per cent. is exceeded in the latter case before a similar result ensues. This is attributed to the presence of oxygen in the gas; but Dr. Wagner has disputed these conclusions on the ground that the experiments were not conducted in a satisfactory manner. He agrees, however, with the statement that a mixture of gas and air possessing fatal properties is necessarily in an explosive condition.

THE PARASITIC NATURE OF MELANOSIS.

A CONCLUSION which will generally be regarded as somewhat extraordinary has recently been arrived at by M. Bard, who believes that a clinical and pathological study of melanosis and certain melanotic tumours is sufficient to prove that these morbid processes and conditions are the result of the action of a parasitic organism. This organism he believes to be no other than the black granules themselves. True, he argues, these granules (and may we add crystalline forms?) do not approximate in character to the majority of known micro-organisms, though he considers that they somewhat resemble the micrococci of actinomycosis.

COCAINE FOR THE SOUDAN.

WE are glad to hear that the National Aid Society has arranged to send a supply of cocaine for the soldiers and sailors in Egypt and the Soudan. This is a thoughtful and commendable step, the costly nature of this drug rendering it otherwise only too likely to be conspicuous by its absence. The Society, to the Princess of Wales's Branch of which the Queen has forwarded a donation of £50 and a case of tobacco, is also sending out nurses, cooking sisters, and a variety of comforts and amusements for the troops.

FROM the report of the examination made by Colonel Sir Francis Bolton of the water supplied by the several metropolitan water companies during the month of February, it appears that the Thames water sent out by the Chelsea, West Middlesex, Southwark, Grand Junction, and Lambeth Companies exhibited, on the whole, a slight increase in the amount of organic matter, the proportion being greater in the water of the Southwark and Grand Junction, and least in that of the Lambeth and Chelsea Companies. The water supplied from the Lea by the New River and East London Companies contained slightly less organic matter than the previous month's samples, the New River Company's supply being in this respect far superior to any of the Thames waters, whilst the East London Company's supply ranked with the best of the Thames waters. All the samples were clear and bright.

FROM the reply of the Local Government Board to a memorial recently forwarded by the North-Western Association of Medical Officers of Health on the subject of revaccination, it appears that the Board are not prepared to propose for the sanction of Parliament an increase in the rate of payment for revaccination relatively to the rate which boards of guardians may appoint for primary vaccination; nor are they prepared to furnish to all medical practitioners lymph for the revaccination of the several persons whom these practitioners may think proper to vaccinate. With regard to this latter point, the Board are satisfied that such revaccinations as are performed in any locality with lymph supplied at the public expense ought to be done as part of the system of public vaccination appointed for the locality.

THE Local Government Board have transmitted to the Isle of Thanet Sanitary Authority the report of Dr. Davies, their medical inspector, on the sanitary condition of that extensive district. It appears from this report that the water-supplies of the villages of Minster, Monkton, and Sarre are derived from shallow wells, many of which the inspector says are liable to pollution. The Local Government Board therefore urge upon the authority the necessity of providing a public water-supply for the villages mentioned under the powers of the Public Health Act.

MR. ADAM SEDGWICK has in preparation a new book, to be entitled "The Elements of Animal Biology," which is intended to serve as an introduction to the study of Animal Morphology and Physiology. Messrs. Swan, Sonnenschein, and Co. are to be the publishers.

SURGEON-MAJOR OLIVER CODRINGTON has been temporarily appointed Assistant Professor of Military Surgery at Netley, in the vacancy occasioned by the departure of Surgeon-Major Tobin for Suakim.

THE *Przeglond* of Lemberg announces that cholera has broken out in the Crimea, and states that the Russian authorities are endeavouring to suppress all publication of details.

THE Eastbourne Board of Guardians have resolved to adopt the suggestion which we mentioned some weeks ago as being advocated by Lady John Manners, and intend providing a mincing machine at the union, for the benefit of the inmates who are old and toothless.

THE International Conference on the Prevention of Cholera in Europe has again been postponed. Signor Mancini has now telegraphed to the various European Governments requesting that the several delegates may be instructed to assemble at Rome on May 1st.

THE American medical journals announce the death, on March 10th, of Dr. Ellerslie Wallace, Emeritus Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia—the chair previously occupied by Dr. C. D. Meigs.

PHOTOGRAPHY AND MEDICAL JURISPRUDENCE.

THE DETERMINATION OF PERSONAL IDENTITY.

BY WILLIAM MATTHEWS, BRISTOL.

IN all books dealing methodically with the topic of medical jurisprudence, attention is directed to that division of the subject which treats of legal identification and its related particulars. The rules and usages by which the procedure is governed are primitive, but of long antiquity. Whether before the accredited officer of the Crown, the county coroner, or before the courts of criminal law, the corporal presence of the individual touching whom the inquiry is on foot is an indispensable preliminary. "If the body be not found, the coroner cannot sit," says Blackstone. "An inspection of the body is the essence of the inquiry," observes Dr. Taylor in the "Principles of Medical Jurisprudence." Upon occasion in the courts of civil procedure also the question of identity becomes the essential feature of the investigation. It is the real issue submitted to the adjudicators. "In such instances," says Dr. Beck, "the whole evidence turns on the question of identity." Stature, temperament, marks upon the person, colour of the hair, colour of the eyes, general resemblances, these have, heretofore, been the ordinary elements of the physiological sort upon which a conclusion has been based.

When and where photographic portraiture was first introduced to the notice of the courts does not clearly appear. Certainly, it has not been received with undeviating reliance; for the photographic presentment in many instances differs very materially to the eye from the personal reality. Witnesses, upon their oath, have sometimes been requested to pronounce upon resemblances from which, under ordinary conditions, they would have shrunk in bewildered uncertainty. Yet when considered from the stand-points (1) of their perfect accuracy of delineation, (2) of their minutely-true reproduction of the proportionate areas occupied by the several features, and (3) of the apparent permanence, in adult life, of those proportionate areas, there would certainly appear to be no inscrutable reason why photographs might not be subjected to tests of a severely scientific nature.

There are three or four indispensable conditions to be accepted by scientists, preliminary to such a consummation. 1. A due recognition of the permanence of the essential particulars of a given face. 2. Of the greater or less divergence of all other faces whatsoever from the permanent particulars of the face in question. 3. The requisite reliability of a unit of admeasurement that shall, similarly, be (*a*) permanent in a given face; (*b*) discrepant, more or less, in all other faces. 4. The accredited presence of a sufficiently undeviating horizontal plane, to afford an available zero or datum line.

Now, in order to sustain the proposition that a given adult face is permanent in its chief particulars, it needs but the obvious reflection—(1) that when a man stops growing the bones of his face stop growing at the same time

as all the rest; and (2) that when the bones of the face cease growing, the several features thenceforward retain in permanence their original *locus in quo*. It should go without saying that the requisite unit of the admeasurement must necessarily be sought in the face itself; for by this expedient the varying magnitudes of photographic portraits are effectually provided for. Hence the adaptability of the coloured circle of the eye for the desired purpose—(1) It is well-defined at its exterior circumference; (2) it is a permanent quantity in a given individual; and (3) its dimensions so materially differ in different persons, that of itself it is an important factor of diversity between photographs that are inherently discrepant. Granted, then, the requisite permanence of the facial perpendicular, and the requisite permanence of the unit of the admeasurement (the diameter of the iris at its exterior rim), it remains but to consider the limitless amplification of the facial diversity. It has been long an accepted hypothesis that the dimensions of an ideally perfect face should consist of certain duplicate and triplicate repetitions of its own elements; yet, nevertheless, that all actual faces are, to a greater or less extent, departures from the given ideal. In strict conformity with this hypothesis it may be pointed out that the endlessly numerous permutations which are everywhere consequent upon the presence of even a few factors of diversity is a matter quite amenable to arithmetic proof. This principle of permutation finds its always familiar illustrations in the "ringing of changes" upon an octave of bells, in the casting of dice, and in the myriads of differing verbal forms that a few vocal articulations have afforded to all the nations of the earth.

In conclusion, the general and special data which have been here set forth appeal in the first instance to the common apprehension of men of intelligence; and, secondarily, to the tests and investigations of experts. As the result of such tests and investigations, it is now confidently maintained that the data and conditions enumerated are trustworthy, and open to proof. The photographic portraits of various public personages, taken after intervals of twenty or more years, and suitably enlarged, have been found to correspond very minutely in admeasurement, whilst in the meanwhile great external change has been going forward in their countenance. On the other hand, a comparison of the portraits of any two distinct individuals, tested under the same rigid conditions, fully justifies the statement that, in such cases, varied and palpable discrepancies will inevitably become manifest.

The physiological facts having been accepted, the formularies of procedure may suitably engage attention. To those to whom the topic is new, an explicit statement of details might prove the more convenient; but summarily and technically, those particulars may be dealt with as follows:—1. Upon a photograph of enlarged magnitude let a right line be drawn from centre to centre of each pupil. 2. From the given centres describe arcs intersecting each other, above and below the right line, of a radius as the distance between the centres. 3. From the points where the arcs cut each other produce the perpendicular. This will, necessarily, be the true facial perpendicular, whatever may be the pose of the sitter. 4. Lay off a parallel on either side of the perpendicular at the distance of the given centres. 5. Lay off a series of parallels, above and below the line of the pupils, and let their measured distance apart be that of *precisely the diameter of the iris*. 6. Let each parallel extend over the right-hand margin of the portrait, and be numbered consecutively. The given line of the pupils being a naught or zero, let the other numbers proceed from it, upward and downward. 7. Reproduce these details upon the second portrait, and thereupon proceed to make the necessary comparison of particulars.

With the aid of the appliance known as the "identiscope," the required comparison can be effected under conditions the most favourable for careful inspection. Reproduced upon lantern-slides, conjoined by the agency of the zero-points, the compared portraits may be projected in combination, upon a scale of magnitude that would cause the most minute discrepancies to stand revealed, in any reputed instance of spurious or assumed identity.

UNIVERSITY OF ABERDEEN.—The Keith medal, instituted in commemoration of the late Dr. Keith, has been awarded to Mr. George Findlay. Clinical and general surgery form the subjects of examination.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF INSPECTORS OF THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

The Sanitary State of Alnwick, by Mr. JOHN SPEAR.[1]—The attention of the Local Government Board has for some years past been conspicuously directed to the sanitary condition of the Alnwick and Canongate urban district, both on account of its excessive mortality and by reason of reports of successive officers of health, who have resigned with exceptional frequency. And finally, the depositions taken at an inquest went to show that the conditions attaching to certain common lodging-houses indicated a state of grave sanitary neglect. The population was 6691 in 1881, and it consists to an unusually large extent of labourers, navvies, tramps, hawkers, and the like, who find accommodation in lodging-houses maintained largely by keepers of Irish nationality. Alnwick has a somewhat important sanitary history. It was inspected in 1849 on behalf of the General Board of Health, and was found to be marked for its wet surface, damp subsoil, and absence of artificial drainage, besides conditions as to arrangement of houses on areas which prevented even the most ordinary circulation of air about them. But in 1850 certain important improvements, including the sewerage of the town, were carried into effect. In 1866 Dr. Buchanan visited the town in connexion with the important report which he subsequently wrote on the relation of phthisis mortality to conditions of soil-wetness, and he found, in addition to the improvements already referred to, that others of importance, including the provision of a public water service, had been effected. But the actual results of these improvements were found to be in the main disappointing in so far as the mortality had been influenced. The general mortality rate had only fallen from 26·2 to 24·7 per 1000; there had been a reduction as to typhoid fever and diarrhœa from 1·35 to 0·87, and from 0·70 to 0·47 per 1000 respectively. But on the other hand, the rate from consumption had risen from 2·83 to 3·30, and that from other lung diseases from 2·80 to 4·05. Mr. Spear now tabulates the mortality returns from a number of specified diseases down to the end of 1883, and it is found that phthisis has made a still further increase in the magnitude of its rate, whereas the rate for other lung diseases remains practically where it was. The fact is, in the first instance, that the works of drainage effected in Alnwick did not, as elsewhere, succeed in reducing the level of the subsoil water beneath the town, and it has been just in proportion to such lowering that the reduction of the phthisis mortality has taken place elsewhere. But although Alnwick effected improvements some thirty years ago, the place has stood still since, if indeed it has not actually deteriorated as regards its sanitary state, and the lamentable account given by Mr. Spear of the crowded courts and alleys; of the absence of control exercised by the authority over the increasing amount of overcrowding; of the mingling together of houses, stables, middens, pigstyes, and the like; of dwellings built right into the damp earth; and of the disgraceful conditions existing in common and other lodging-houses, amply suffice to explain why a disease such as phthisis, which is so favoured by the conditions of crowding and want of fresh air referred to, has increased rather than diminished. The report embodies a long description of places such as have been referred to; and although it also contains an account of some excellent dwellings erected for the poor and of baths and washhouses, all provided by the Duke of Northumberland, yet such improvements are all but ineffectual in the face of the long-standing sanitary neglect in other matters. The secret of the neglect as regards house accommodation is, however, apparent from the report itself. Individual interests among members of the Town Council have paralysed the sanitary administration. This is why, according to Mr. Spear, so many dwellings entirely unfit for habitation are not dealt with; why building and rebuilding in crowded yards cannot be effectively stopped; why

[1] To be purhased of Knight and Co., 90, Fleet-street; Shaw and Sons, Fetter-lane; Haddon, Best, and Co., West Harding-street; and P. S. King and Son, King-street, S.W.

stables, middens, piggeries, and a hundred other nuisances remain undealt with. And even where nothing but a trivial alteration is needed the authority appears to stand idle. Thus, notwithstanding the immense danger now known to attach to a system by which there is a direct connexion between the interior of watercloset pans and the interior of the water mains, the sanitary authority have failed to take the necessary remedial action. And why? Because, says Mr. Spear, it would have required owners of property to provide so small a thing as the necessary flushing boxes for closets, and, "shrinking from this duty," they have "staked the health of the whole town on a mere chance." It is lamentable in these days, when so much importance is attached to the extension of the principle of local self-government, to read a report like this, in which, notwithstanding recurring elections to the Town Council, such a town as Alnwick can so long have had an authority tolerating such neglect as is now recorded, and all because those whose duty it is to act for the public benefit have "failed to hold the balance justly between individual interests and the interests of the town." In so far as the housing of the poor is concerned, it is to be hoped that Sir Charles Dilke has brought this report under the notice of his fellow-commissioners, and there are other respects in which the case merits the attention of the central government.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

King's Norton Rural District.—Exclusive of deaths of non-residents in public institutions, this district had in 1884 a death-rate of 14 per 1000, the zymotic rate being 0·8 per 1000. Although there was much small-pox in Birmingham during the year, no spread occurred in this rural district. Occasional importations were isolated in hospital, and, for the rest, the district has been protected, as the result of the efficient labours of the vaccination officer. Scarlet fever was also isolated in hospital, and, although twenty-four cases came under observation, no death occurred. The need for such construction of ashpit privies as will be free from nuisance is evidently very great, and Mr. Hollinshead is looking for the remedy in the new bye-laws which are under preparation. These will, of course, only affect new structures; but where sanitary authorities issue new diagrams and plans showing the form of closet permissible under bye-laws, it is astonishing to find how many of the older closets are in time altered according to the pattern indicated. It must, however, be remembered that a proper closet implies a small receptacle for filth, and the latter necessitates frequent removal of contents. Where an adequate system of scavenging is not in operation, people will never put a proper limit on the capacity of their privies, and before the new closets are constructed we advise the authority themselves to arrange a scheme which shall give every house at least a weekly visit, wherever the population is considerable.

Huddersfield Urban District.—During the fifty-three weeks included in the statistical year 1884, the death-rate for Huddersfield was 19·5 per 1000, and it is evident that on a long series of years there has been steady improvement in this respect. The rate from the seven principal zymotic diseases was 3·15 for the previous six years; in 1884 it was 2·38. The diarrhœa death-rate for the third quarter of the year, although not absolutely high, was nearly a tenth of the total mortality for that quarter, and it is to the high temperature and scanty rainfall that the result is in the main attributed by Dr. Cameron. But diarrhœa was more prevalent in 1882 than it was in 1884, and possibly this was due to the precautionary measures now adopted. Wherever a fatal case of diarrhœa was heard of, hose and pipes were at once sent to flush out the local drains, and all accumulations were at the same time removed. Thus, in an important sense the drawback attendant upon scanty rainfall was made good by the authority's officers. Enteric fever also became prevalent in the fourth quarter of the year; but the system of notification worked well and smoothly, and the great improvement effected in the hospital provision came in useful. Of 67 cases reported, no less than 47 were admitted into the Birkby Hospital, and following on this came a system of disinfection for the local drains. Under the compulsory Act, 234 cases were reported. Of these, 118 were cases of scarlet fever, and 94 of them were removed to hospital. The Act is again reported to have worked smoothly. The system of house-to-house inspection which has been in operation, and which is so deservedly regarded as one of the most important duties which sanitary officers can carry out, was temporarily suspended owing to changes in the staff. Much valuable work of a very similar sort was, however, effected as the result of the information acquired by the system of notification.

Brentford Urban District.—Sewers have now been laid throughout the district, and during the past year the work of making the house connexions has been in progress. At the same time sanitary defects which these works disclose are remedied, cesspools are filled in, and other sources of danger to health are abated. Some nuisance having been experienced from the sewer manholes, ventilating shafts have been erected, and during the warm weather hand flushing was resorted to. A first step has been taken to provide means of isolation by the erection of a Doecker hospital hut, but the present site is not regarded as permanently decided on. The annual death-rate was low—namely, 12·28 per 1000; that from the principal zymotic diseases was 1·2 per 1000. The estimated population is 12,307.

Holsworthy Rural District.—On a population of some 9000 the birth-rate for 1884 was 30·8, and the death-rate 16·5 per 1000. The only deaths coming within the group of the principal zymotic diseases were 4 from diarrhœa and 6 from whooping-cough. During the spring and early summer a smart epidemic of sore-throat, which Mr. Linnington Ash did not regard as diphtheritic, occurred in Holsworthy town. It was attributed to emanations from the sewers, the gully traps having become unsealed in the streets, owing to the combined effect of drought and strong north-east wind. In Ashwater much the same sort of disease occurred during the third quarter of the year. The affection was distinctly infectious, but it was not regarded as either diphtheria or scarlet fever. It caused no deaths. Improvements as to the water-supply of the district are steadily in progress, but much remains to be done in this respect, especially in Holsworthy town, which is dependent on surface wells liable to become dry during drought, and is also subject to the risk of pollution. This matter has been referred to before in the annual reports, and the time has come when the authority should take it in hand with a view of providing the inhabitants with a proper supply of one of the first necessaries of life.

Llanelly Rural District.—Dr. Raglan Thomas reports a diminution in the amount of epidemic prevalences, and in part he regards this as due to the system of paying a small fee to medical practitioners who have voluntarily reported fresh outbreaks. When such reports come in a searching inquiry is at once made, as is indeed indicated by a lengthened tabulated *résumé* of the conditions discovered. It would be still more interesting if, on future occasions, a column were to indicate the action which had been taken as the result of the discoveries made. Bye-laws now provide for the removal of all privy accumulations twice a week, but, as is often the case, people who are without sufficient garden ground are unable to comply with the regulation. Where this is the case the authority should regard it as its own duty to effect the scavenging with the needed regularity and frequency, instead of imposing the obligation on occupiers. A curious instance of water poisoning by zinc came under notice in connexion with the use of the Cwmfelin water. A very pure water had, by virtue of the dissolved oxygen and carbonic acid naturally present in it, taken up 6·4 grains of carbonate of zinc per gallon. This result, which is described by the analytical chemist as unique in his experience, was brought about by the use of so-called "galvanised" water pipes. Boiling causes precipitation of the zinc. Dr. Thomas still deplores the absence of an infectious hospital in his district. The death-rate for 1884 was 15·6 per 1000 living.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN twenty-eight of the largest English towns 5872 births and 3967 deaths were registered during the week ending the 28th ult. The births exceeded by 58, and the deaths by 340, the average weekly numbers during 1884. The annual death-rate in these towns, which had been equal to 20·6, 22·1, and 23·5 per 1000 in the preceding three weeks, declined again last week to 23·2. During the first twelve weeks of this year the death-rate in these towns averaged 22·6 per 1000, against 24·6, the mean rate in the corresponding periods of the nine years 1876-84. The lowest death-rates in these towns last week were 17·8 in Portsmouth,

18·0 in Derby, 18·5 in Bradford, and 18·7 in Brighton. The rates in the other towns ranged upwards to 31·2 in Manchester, 31·7 in Newcastle-upon-Tyne, 33·9 in Oldham, 40·4 in Sunderland, and 41·9 in Cardiff. The deaths referred to the principal zymotic diseases in the twenty-eight towns, which had increased from 377 to 443 in the previous four weeks, further rose to 451 last week; they included 176 from measles, 124 from whooping-cough, 37 from "fever" (principally enteric), 37 from diarrhœa, 31 from scarlet fever, 25 from small-pox, and 21 from diphtheria. No death from any of these zymotic diseases was recorded last week in Brighton, whereas they caused the highest death-rates in Newcastle-upon-Tyne, Cardiff, and Sunderland. The highest death-rates from measles occurred in Huddersfield, Newcastle-upon-Tyne, Cardiff, and Sunderland; from whooping-cough in Preston, Cardiff, and Oldham; and from "fever" in Newcastle-upon-Tyne, Preston, and Norwich. The 21 deaths from diphtheria in the twenty-eight towns included 11 in London, 3 in Cardiff, and 2 in Portsmouth. Small-pox caused 47 deaths in London and its outer ring of suburban districts, 2 in Sunderland, 1 in Manchester, and 1 in Newcastle-upon-Tyne. The number of small-pox patients in the metropolitan asylum hospitals situated in and around London, which had declined in the preceding five weeks from 1223 to 830, had increased again to 865 on Saturday last; and the admissions, which had been 94, 104, and 137 in the previous three weeks, further rose to 179 last week. The Highgate Small-pox Hospital contained 94 patients on Saturday last, the admissions in the week having been 31, a higher number than in any previous week of this year. The deaths referred to diseases of the respiratory organs in London, which had been 374, 455, and 487 in the preceding three weeks, declined again to 448 last week, and were 69 below the corrected weekly average. The causes of 121, or 3·1 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Norwich, and in three smaller towns. The largest proportions of uncertified deaths were registered in Halifax, Preston, Hull, and Sheffield.

HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 24·4 and 24·2 per 1000 in the preceding two weeks, further declined to 23·3 in the week ending the 28th ult., and was almost identical with the rate (23·2) during the same week in the twenty-eight large English towns. The rates in the Scotch towns last week ranged from 10·6 and 14·1 in Leith and Greenock, to 22·0 in Paisley and 29·9 in Glasgow. The 568 deaths in the eight towns included 32 which were referred to whooping-cough, 18 to measles, 12 to diarrhœa, 6 to "fever," 4 to scarlet fever, 1 to diphtheria, and not one to small-pox; in all, 73 deaths resulted from these principal zymotic diseases, against 88 and 85 in the preceding two weeks. These 73 deaths were equal to an annual rate of 3·0 per 1000, which was 0·4 above the mean rate from the same diseases in the twenty-eight English towns. The deaths from whooping-cough, which had been 22 and 35 in the preceding two weeks, were 32 last week, and included 17 in Glasgow, 5 in Dundee, and 3 in Greenock. The 18 fatal cases of measles showed a decline of 10 from the number in the previous week; they all occurred in Glasgow. The 12 deaths attributed to diarrhœa showed an increase of 6 upon the number in the previous week, and exceeded by 3 the number in the corresponding week of last year. The 6 deaths referred to "fever" included 3 in Edinburgh and 2 in Glasgow; while all the 4 fatal cases of scarlet fever occurred in Glasgow. The deaths referred to acute diseases of the respiratory organs in the eight towns, which had been 122 and 124 in the previous two weeks, were 122 last week, and exceeded the number in the corresponding week of last year by 5. The causes of 71, or more than 12 per cent., of the deaths in the eight Scotch towns last week were not certified.

HEALTH OF DUBLIN.

The rate of mortality in Dublin, which had been equal to 32·7, 39·5, and 34·6 per 1000 in the preceding three weeks, further rose to 40·4 in the week ending the 28th ult. This is a higher rate than has prevailed in any previous week of this year. During the first twelve weeks of this year the death-rate in the city averaged no less than 34·1 per 1000; the mean rate during the same period did not exceed 21·6 in London and 20·3 in Edinburgh. The 273 deaths in Dublin last week showed an increase of 39 upon the number in the previous week, and included 32 which were referred to the principal zymotic diseases, against 30 in each of the preceding two weeks. Of these 32 deaths, 12 resulted from measles, 7 from scarlet fever, 6 from "fever" (typhus, enteric, or simple), 3 from diphtheria, 2 from whooping-cough, and 2 from diarrhœa. The annual death-rate from these principal zymotic diseases was equal to 4·7 per 1000; whereas the rate from these diseases last week did not exceed 2·5 in London and 1·7 in Edinburgh. The fatal cases of measles in Dublin, which had been 11 and 16 in the previous two weeks, declined again to 12 last week. The deaths from scarlet fever and diphtheria, on the other hand, exceeded those returned in any recent week. The 6 deaths from "fever" showed an increase of 3 upon the low number in the previous week. Seven inquest cases and 8 deaths from violence were registered within the city; and 85, or nearly a third, of the deaths were recorded in public institutions. The 51 deaths of infants exceeded the number in any previous week of this year, and those of elderly persons were also numerous. The causes of 38, or 14 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

We understand that in view of the necessity for an increase in the Army Medical Staff, the Secretary of State for War has decided to grant appointments to all the candidates who, at the late competitive examination, obtained the necessary qualifying marks, but were excluded in consequence of being beyond the number required to fill vacancies. This will provide an addition of about thirty-eight officers to the Department.

We note that a telegram having been received recently by Her Majesty's Secretary of State for India from the Government of India, requesting that all officers in military employ on furlough may be directed to rejoin their regiments or appointments, instructions to this effect were issued on the 25th ult. to all medical officers, as also to combatant officers, of the Indian army to proceed to Brindisi in time to join the Peninsular and Oriental Company's mail steamer there on the 6th inst.

INDIA OFFICE.—The Queen has approved of the following admissions to her Majesty's Indian Medical Service:—John Tasman Waddell Leslie, David Prain, Arthur Thomas Bown, Upendra Nath Mukerji, and William Locking Price, to be Surgeons in the Bengal Army.

ADMIRALTY. — The following appointments have been made: Staff-Surgeon James Dunlop, M.D., to the *Ruby;* Surgeon Herbert Canton, to the *Ruby;* Staff-Surgeon Albert C. Traceby, to the *Mercury;* Surgeon Edward R. T. Fasker, to the *Shannon*, additional; Surgeon Edward H. Williams, to the *Cockatrice;* Surgeon Penrose J. Barcroft, to the *Imogene;* Herbert M. Sweetman to be Surgeon and Agent at Schull; and Francis Rennie, M.B., to be Surgeon and Agent at North Shields; Staff-Surgeon Albert C. Queely, to the *Mercury;* Thomas W. Fryer to be Surgeon and Agent at Gerran's Bay; George W. Hill to be Surgeon and Agent at St. Mawes and St. Anthony.

ARTILLERY VOLUNTEERS.—1st Lancashire: Thomas Moore Dawson, Gent., to be Acting Surgeon.

ENGINEER VOLUNTEERS.—1st Newcastle-on-Tyne and Durham: Surgeon John Wilson resigns his commission.

RIFLE VOLUNTEERS. — 1st Clackmannan and Kinross: Feter Rough, Gent., M.A., M.B., to be Acting Surgeon.— 2nd Volunteer Battalion, the Lincolnshire Regiment: Surgeon and Honorary Surgeon-Major Edwin Morris, M.D., resigns his commission; also is permitted to retain his rank, and to continue to wear the uniform of the battalion on his retirement.

THE LATE GENERAL GORDON.—We understand that the *Boy's Own Paper*, of the Religious Tract Society, whose readers have already subscribed over £1200 for two lifeboats, besides £400 for a hospital cot, is promoting a Boys' Gordon Memorial on the lines known to be dear to Gordon himself—viz., to help the poorer working and suffering lads.

Correspondence.

"Audi alteram partem."

THE NEW EDITION OF THE NOMENCLATURE OF DISEASES.

To the Editor of THE LANCET.

SIR,—The second edition, being the first revision of "The Nomenclature of Diseases," is now in the hands of the profession. A memorandum of the Subcommittee on Classification inserted therein quotes the first line of the preface of the first edition, which declares "the perfecting the statistical registration of diseases" to be the object of the undertaking, and then significantly adds, "this object has certainly not been as yet attained." I think the bulk of the profession will so far agree with the subcommittee in this expression of opinion, for it will doubtless assume that the prefatorial memorandum was written, as is customary, after the rest of the work was in type.

"To-morrow the critics will commence—men who have failed in literature and art," some members of the subcommittee may possibly say, quoting Lord Beaconsfield. To them the painstaking registrar will reply, in the words of a still greater authority, "I am nothing, if not critical."

May it not be possible, for instance, for cases of "frost-bite" to occur in this variable climate of ours? One such accident comes under the notice of our conscientious statistician, who wishes to notify the same in an orderly manner. He turns to his copy of "The Nomenclature," which a parental Government has just forwarded him, and looks out "frost-bite" in the index. He is referred to pp. 193, 215, 217, 223. He opens the volume at p. 193, and finds the ailment in question placed under diseases of the skin. He turns to page 215, and perceives it inserted under general injuries with a note as to its limitations. At page 217 it is placed amongst the local injuries, and at page 223 along with injuries to the skin. If this arrangement (?) is insufficient to produce the bewilderment necessary for statistical purposes in the brain of our conscientious statistician, I may yet add a further section, wherein "frostbite" can have a place, and that will be found at page 12—"Effects of cold." Somewhat similar results would be the outcome of attempts to classify the other "effects of climate, &c." recorded in the nomenclature. I shall not, however, encroach on your valuable space by recapitulating them.

A casual perusal of the volume in question has, however, brought to light the following further peculiarities—e.g.: Alcoholism (p. 12) is a disease of diet; alcohol (chronic poisoning by) (p. 203) is included among the poisons; mercurial tremor may be either a disease of the nervous system (p. 27), or the result of a poison (p. 199); syncope is both a disease of the nervous system (p. 29) and one of the circulatory system (p. 71); ranula occurs twice (pp. 89—99); chromium is the only metal whose salts are given in the section (p. 199); phosphorous acid is a poison; nitrous and sulphurous acids are not given (p. 201); sulphate of indigo is named (to use a parliamentary expression) in the short list of poisonous acid salts (p. 201); picric acid is called by the discarded name carbazotic acid (p. 203); elephantiasis (p. 123) is classified as a proliferation tumour, whether it is evidently caused by the presence of the parasite filaria sanguinis or not; we also learn that this disease is a variety of "diffuse fibroma" (p. 309); tubercle is a variety of granulation tumour (p. 313); gonorrhœa is a disease of the whole body (p. 11); gleet (gonorrhœa mucosa) is a disease of the male organs of generation, unless it is caused by gonorrhœa (p. 135). In the first edition, gonorrhœa was placed amongst diseases of the urinary system. "Amyloid," the synonym of the rarely-used term "lardaceous," is frequently omitted—e.g., pp. 3, 105. The following diseases and synonyms are omitted: Comedones, area Celsi, Duchenne's paralysis, Jacksonian epilepsy, amyotrophic lateral sclerosis, and many other well-known nervous diseases. Fetid bronchitis, malignant endocarditis, peritonitis due to gonorrhœa, perimetritis and parametritis are not inserted in the index, although they occur on page 147.

Many fairly common poisons are also omitted—e.g., croton chloral hydrate, paraldehyde, &c. Finally, "morula" (O tempora! O morula!) is the Latin equivalent for "yaws." One would almost imagine that our classic must have been pleading with the printer's devil for a "brief respite" from the latter's too persistent visits for "copy" when he substituted "morula" for the time-honoured "framboesia," although the latter's derivation from the French (alluded to by Bateman) is scarcely classical.

I am, Sir, yours obediently,

Brighton, March 30th, 1885. W. AINSLIE HOLLIS.

FORENSIC MEDICINE.

To the Editor of THE LANCET.

SIR,—I have waited in the hope of seeing letters from more experienced writers and abler pens than mine confirming the remarks of your able leader of March 7th. There are, according to the Medical Directory, fifty-one medical coroners in England and Wales out of a total of 281. The subjects of forensic medicine and coroners' inquests penetrate every nook and cranny of medical practice in England, Wales, and Ireland; and, though there is no coroner's inquest in Scotland, the subject of forensic medicine has received more practical attention there than in any other part of the United Kingdom. I am surprised, therefore, that no notice has as yet been taken of your leading article by some of the many who are so capable of dealing with it. Having in the course of the last twenty years made many post-mortem examinations for different coroners, and taking great interest in all medico-legal cases, I am in a position to confirm the remarks in the second part of your article.

There is a very forcible reason why two examiners should always be employed in cases involving a criminal charge, which you have omitted to notice. One may be ill or even dead when the trial comes on, and if he has been unassisted there is no one to give evidence or to be cross-examined. It is true that the depositions before the coroner and magistrate are in court and can be read, but anyone who has attended trials must know what a very unsatisfactory substitute for a witness are his depositions.

Another point which can hardly be ignored is the importance of a division of time and labour. I know nothing more fatiguing than making a post-mortem examination of an adult corpse, completely and satisfactorily, by oneself. Even in a hospital dead-house, with every convenience, it means time and work; but in the dwellings of the poor, without any convenience whatever, and with the body lying on the floor, it becomes as hard a task as can well be undertaken.

The importance of expert evidence in criminal cases will be seen by a reference to recent trials. In the Penge case the question was simply, Did the deceased die from starvation or natural causes? and had there been present at the autopsy one of the many experienced pathologists attached to the metropolitan medical schools, most of the difficulties of the case would have vanished. In two cases which occurred recently in Manchester, the evidence of Dr. Cullingworth, the lecturer on Forensic Medicine at Owens College, was most important; strengthening the case for the prosecution in one and disproving a groundless charge in the other. And in all cases which are likely to proceed to a higher court it is obviously desirable that the coroner and medical witness should have the benefit of a second opinion—i.e., of an expert, well experienced in post-mortem examinations, and with a competent knowledge of forensic medicine.

Another matter which you have not noticed is that the coroner in a certain proportion of the cases which come before him has absolute discretionary power in the selection of a medical witness, none having been called in either before or after death. Hence, in all these, he is at liberty to employ an expert without any encroachment upon the rights of general practitioners. And it is these unappropriated cases, as they may be called, which might be utilised for the study and practice of forensic medicine. In 1861 the chair being then vacant, the late Dr. Ayrton, who was generally chosen by the coroner at that time to make all post-mortem examinations for him, was appointed the lecturer on medical jurisprudence at our local medical school, and it was hoped that the appointment would enhance the interest of the lectures. Dr. Ayrton only lectured, however, for one session, and the experiment was abortive. In a paper read before our medical institution in 1876 on the "Coroner's Court," I attempted to show how it

might be rendered more effectual in providing "the more efficient performance of all medico-legal autopsies and a field for the practical study of forensic medicine in our medical schools." Referring to the latter, I observed, "In a word, every department of medicine should be taught and learned 'practically.' Why should forensic medicine be any exception to the rule? Within a distance of very little over a mile from the Royal Infirmary is a place which affords a field for the practical study of forensic medicine little inferior to the Morgue of Paris, where world-renowned medical jurists, Orfila, Devergie, and others, acquire their reputation. I refer to the dead-house, Prince's Dock, where cases of death from drowning, burning, suffocation, exposure to cold, and infanticide, may be seen in almost every variety. ..... Now, without encroaching upon other gentlemen's province, the students of the Royal Infirmary School of Medicine (now the Medical Faculty, Liverpool University College) might have many opportunities afforded which they do not now possess. During the summer session the lecturer on forensic medicine might, I am sure, easily obtain permission of the authorities to visit this place and show the external appearances of death from the various causes I have indicated as to be met with there." The suggestion was favourably received by those present at the meeting, which included Dr. Ewing Whittle, then, and until very recently, lecturer on medical jurisprudence. But changes are not easily made, and so far nothing has been done. Mr. F. T. Paul, a most experienced pathologist, has just been elected to the vacancy, and I trust that he will be afforded every reasonable opportunity of both practising and teaching forensic medicine.

With regard to toxicology, it seems to me to be very important that students should be taught the detection of poisons in urine, vomited matters, &c., although the more elaborate examination of these, as of viscera, must be left to the analytical chemist. But the medical practitioner is the first on the spot, and it is his accurate observation of facts and symptoms which leads to detection. In the Edinburgh opium poisoning case, which occurred some years ago, it was reported that some spots on the nightdress of the deceased were detected by the chief medical witness as caused by laudanum having been spilled. This single fact proved a most important piece of evidence, as the case presented all the usual difficulties of opium poisoning. In the Lamson case the careful preservation and analysis of the matters first vomited were the most important links in the chain of evidence against the prisoner. Much, if not all, the mystery of the Bravo case would have been dispelled by a careful analysis of the urine, fæces, and vomited matters while the unfortunate deceased was still living. More important than analysis is the careful observation of symptoms, and comparing them with those of poisoning. In the recent cases of murder by arsenic in this city it was shown by the confession of one of the prisoners that eleven deaths were due to arsenic administered by one or both of the accused persons. All these persons had been attended by medical practitioners, and the deaths had been duly certified. How many more victims might have fallen had not the death of Thomas Higgins excited Dr. Whitford's suspicion, it would be hazardous to guess; but the case shows the importance of careful observation. It was the sudden nature of the death which excited Dr. Whitford's suspicion, though in the miserable surroundings of the case he failed to see any motive for foul play until he heard that the life of the deceased, a poor bricklayer's labourer, was insured to the extent of £100.

I could have added more were this letter not already too long. I conclude with the hope that the defects you have indicated will be remedied, and that forensic medicine will become, as so interesting a subject deserves to, a thoroughly practical and attractive branch of medical study.

I am, Sir, yours faithfully,

Liverpool, March 25th, 1885. FRED. W. LOWNDES.

PHYSIOLOGY IN OXFORD.

To the Editor of THE LANCET.

SIR,—You have thought fit to accuse those who recently opposed the grant to the Physiological Laboratory at Oxford of misrepresentation, recklessness, injustice, and an unwarrantable use of personal allusion. As all the circulars and notices issued by the opponents of the grant passed through my hands, I ask you to allow me to repudiate your accusation as emphatically as possible, and in enclosing you the documents in question I challenge you to point out one single sentence containing a misrepresentation, a reckless or unjust statement, or any personal allusion which an official position does not warrant. Two concessions only were asked of Professor Sanderson—viz., that he would not hold a certificate to dispense with anæsthetics, nor one to free him from the necessity of killing the animal.

Now, if the promoters of the grant had said openly, "Away with such restrictions and concessions; they are an insult!" the opponents of the grant, however much they might have regretted such a declaration, would have respected it as the bold challenge of a candid antagonist. But in the circular issued in advocacy of the grant, and in the debate in Convocation, the arguments used were, "There are to be no painful experiments on living animals, either with or without anæsthetics. The grant is only for coal, gas, and water." You, Sir, know well that there may and will be painful experiments on living animals without anæsthetics within that laboratory *for purposes of research*, and to say, as was said, "There will be none for purposes of demonstration and instruction," and at the same time to suppress all allusion to experiments for research, is an act of "aggressive concealment" unworthy of those who believe they have a good case.

I am, Sir, your obedient servant,

FREDERIC E. WEATHERLY, M.A.

Brasenose College, March 28th, 1885.

*** Mr. Weatherly cannot be ignorant of the fact that the cause he advocated received some of its most powerful support from others than those immediately concerned in the voting at Oxford. Our remarks did not apply to the phraseology of the circulars with which he has favoured us.—ED. L.

INSANITY AFTER OVARIOTOMY.

To the Editor of THE LANCET.

SIR,—It would seem desirable that every case in which ovariotomy has been followed by insanity should be recorded.

Some years ago, in Sydney, I removed a large ovarian cystoma from a widow aged about forty. I have not brought the notes of the case with me, and cannot therefore give her exact age. Three days after the operation she became insane, and, unlike most of the cases related by the speakers upon this subject at the last meeting of the Clinical Society, the disease became chronic, and it was found necessary to confine the patient in the asylum at Gladesville. The disturbance of the mental balance in this case, I thought, was due to the sudden and violent change from extreme mental depression to excessive joy. The patient had quite made up her mind that she should die under the operation, and had given directions as to the conduct of her funeral. Her extreme astonishment when she recovered from the effects of the anæsthetic at finding that she was not only living, but rid of her burden, I shall not soon forget. I should state that there was no family history of insanity.

I am, Sir, yours obediently,

Sydenham-hill, March 30th, 1885. P. SYDNEY JONES.

HICKS *v.* BEDFORD AND OTHERS.

To the Editor of THE LANCET.

SIR,—Dr. Rogers, in his interesting letter published by you on March 21st relating to this case, draws attention to a very important passage in Mr. Justice Wills' charge to the jury. The quotation given is that "there is no statutory power whereby anyone, lunatic or otherwise, can be detained in a workhouse against his will." As Dr. Rogers points out, this ruling must cause a very great surprise to those concerned in workhouse administration, as it declares illegal a practice which has gone unchallenged for upwards of forty years at least. But this particular paragraph, at any rate, is not in accordance with the Poor-law Amendment Act of 1867, 30 & 31 Vict., sec. 22 of which states: "When there shall be in any workhouse a poor person suffering from mental disease, or from bodily diseases of an infectious or contagious character, and the medical officer of such workhouse shall, upon examination, report in writing that such person is not in a proper state to leave the workhouse with-

out danger to himself or others, the guardians may direct the master to detain such person therein, or, if the guardians be not sitting, the master of the workhouse may, until the next meeting of the guardians, detain him therein, and *such person shall not be discharged from such workhouse until the medical officer shall in writing certify that such discharge may take place;* provided, however, that this enactment shall not prevent the removal of a lunatic to a lunatic asylum when such removal is otherwise required by law, nor the removal of any poor person after the parent or next of kin of such person shall have given to the guardians such an undertaking as they shall deem satisfactory to provide for the removal, charge, and maintenance of such person with due care and attention while the malady continues."

It is the practice at the Stoke-on-Trent Union Workhouse, where I am medical officer, for certificates to be signed by myself, the master, and the clerk to the guardians, when it is thought necessary to detain any person suffering from mental or infectious disease, and I have on more than one occasion thus detained patients convalescing from scarlet fever and cases of delirium tremens. I enclose our form of certificate, which is drawn up in strict accordance with the Act of Parliament.

I am, Sir, yours obediently,

Stoke-on-Trent, March 30th, 1885. J. G. UVEDALE WEST.

THE HISTORY OF THE USE OF IPECACUANHA IN DYSENTERY.

To the Editor of THE LANCET.

SIR,—Dr. Macpherson's paper on the above subject, read at the meeting of the Medical Society on March 9th, was one of great interest. It would appear, however, that it was left to Sir Joseph Fayrer to recall the fact that it was to Mr. Docker we owed the introduction of the remedy into the practice of the British army and the reduction of its employment to a system. Sir Joseph Fayrer was right in thus giving honour to whom honour is due; for, although something may be credited to improved sanitation, &c., there is no doubt that the great decrease in the mortality from dysentery in India in late years is due to the employment of the system of treatment introduced by Surgeon-Major Docker.

Having treated a large number of cases of dysentery with ipecacuanha, in large doses, during my service in Ceylon, India, and British Burmah, I can bear testimony to its great efficacy in acute cases, a few twenty-grain doses bringing the disease promptly to a termination, when treated at an early period, as stated by Sir Joseph Fayrer. I can also bear out Dr. Cullimore's belief that "in dysentery associated with hepatic disease ipecacuanha, in large doses, is not well borne." Dysentery is frequently found associated with, or dependent on, hepatic congestion. My latest experience of the treatment of such cases was given in a paper in the *Indian Medical Gazette* of July 1st, 1881; and as the passage bearing on the treatment of this complication is short, and the subject one of much interest, I beg leave to quote it:—"When dysentery is present, complicating the hepatic congestion, I have found the treatment suggested at page 52 of my book successful—viz., a mixed treatment of alternately giving ipecacuanha (twenty to thirty grains) and chloride of ammonium until the relief of the dysentery, or a full midday dose of ipecacuanha, or the latter in enemata should there be fear of vomiting, with morning and evening doses of the chloride, or in some cases a midday dose of the chloride may be preferable, and morning and evening doses of the ipecacuanha, until the dysentery is checked. In such cases the patient, if asked, will express himself as receiving great relief from pain by the exhibition of the chloride; and, if so, it may be well to give it more frequently than here recommended."—I am, Sir, yours, &c.,

WM. STEWART, M.D.,
Surgeon-General, A.M.D. (retired).

Mount Pleasant, Lymington, March 23rd, 1885.

AN anonymous donor has intimated to the Committee of the Sheffield Hospital and Dispensary his desire to endow a bed in the institution, in memory of the late General Gordon, on condition that it shall be known for ever as the "Gordon Bed." The endowment is thirty guineas a year, which the donor will pay for some time, and then invest capital with trustees sufficient to raise the amount annually required in perpetuity.

THE GORDON MEMORIAL HOSPITAL.

(From a Correspondent.)

THE choice of Port Said for the proposed establishment of a Gordon Memorial Hospital appears to be adversely commented on by professional and public opinion in Egypt. It is strongly urged that by far the most suitable place is Alexandria. It is the seaport of Egypt, the centre of commerce, and has a population of nearly 200,000.

Port Said is an outlandish insanitary little town, with only 12,000 people, of whom about six families are English. There is no highway to it from any part of Egypt except from Suez by the Canal, and ships passing through the Canal do not stop at Port Said. Nor is there any railway communication with it, so that a hospital there could benefit only an odd seaman landed from a passing vessel, or, perchance, a stray traveller.

In Alexandria, on the other hand, with its extensive shipping, as the import and the export city of Egypt, a large number of British seamen every year are landed for resident treatment in a hospital. For this they have to depend on foreign institutions, and are attended by nurses that do not always speak their language. English residents, also, in the towns and villages of Egypt, that have no real home where they can be attended to during sickness, go to hospital in Alexandria as the commercial centre, and could not go to Port Said for want of railway communication.

In Alexandria the English residents contribute most liberally to a foreign hospital. In it hundreds of merchant seamen, many officers and men of the British Army and Navy, and Englishmen without home comforts, are treated by the English doctor, who is one of the visiting surgeons. In the same hospital, and by the same doctor, 200 or 300 Egyptians are treated annually as in-patients, besides some 20,000 out-patients. This success is almost entirely due to the ability and energy of the English doctor. Natives (Egyptians, Bedouins, and Soudanese) flock from far and near, attracted by the reputation that English surgery has won in his hands; and while they gravitate to a centre like Alexandria, with a surgical fame already declared, they never would go to Port Said, where the essentials of success do not exist, and where a fine institution, after an ineffectual flicker, would soon dwindle down into a fourth- or fifth-rate cottage hospital.

The success in attracting natives is a most important point, for it must be remembered that Gordon, to whose beloved and honoured memory a hospital is to be erected in Egypt, was, above all things, catholic, and gave his life for Mussulmans.

It is to be hoped that this matter will receive the anxious consideration of the Memorial Committee, if they desire an institution that will really honour the blameless and heroic life of General Gordon, and that will be a credit to its founders.

NORTHERN COUNTIES NOTES.

(From our own Correspondent.)

DR. DALLINGER IN NEWCASTLE.

DR. DALLINGER delivered a lecture last week in our Literary Philosophical Institute which will not be soon forgotten. The subject, I need scarcely say, was treated in a most masterly and advanced manner by the reverend lecturer. The title of his subject was "On a New Putrefactive Organism, with some Deductions concerning the Group," but the mere title gives but a faint idea of the extent of ground covered by the reverend and learned lecturer's discourse, which was of a deeply interesting character, and well illustrated by the oxyhydrogen lantern. He showed certain nomads that he had discovered by a powerful microscopic lens, rectified by the modern employment of various essential oils as corrective media of refractive errors. He dwelt principally on septic organisms, and went fully into the source and life of these nomads, how they were produced in water where animal matter was

decomposed, and by such decomposed animal matter became reproduced into a new form of life. He urged upon biologists of the district the study of the bacteria, so that the various forms might be followed out, and the fullest information on the subject obtained, which, he said, was of the greatest importance to the human race.

THE FLEUSS APPARATUS.

The local papers are much taken up with letters and inquiries about the Fleuss apparatus. It is felt that if such had been in readiness after the explosion at Usworth the lamentable loss of life by the intrepid explorers might have been avoided, and possibly lives in the future rescued by its adoption. It has been sufficiently shown that the Fleuss apparatus enables its wearer to remain under water or in an unrespirable atmosphere for as long as an hour and twenty minutes. The Fleuss apparatus may be in its essentials thus described. It consists of a mask or mouth-piece, a knapsack, and an elastic bag or air reservoir. The mask fits tightly over the eyes, mouth, and nose, and is held in position by means of straps fastened at the back of the head. The knapsack comprises the gas chamber and the alkali chamber. The gas chamber is a strong cylinder made of sheet copper, 12 in. long and 8 in. diameter, and will contain four cubic feet of oxygen gas at a pressure of 58 lb. per square inch. The alkali chamber is contained in a tin plate case, and is made of vulcanite 12 in. high, 12 in. wide, and 6 in. deep, divided vertically by diaphrams so disposed as to cause the exhaled air to pass through the caustic alkali twice before it is delivered into the fresh air reservoir deprived of all the carbonic acid gas, and the greater part of the moisture or aqueous vapour of the breath. The fresh air reservoir is made of vulcanised indiarubber, which admits of a pulsating movement corresponding to the breathing of the wearer. It is worn on the front of the body extending over the chest and stomach. A flexible inhaling tube is carried over one shoulder and connected to the air reservoir, and the flexible exhaling tube is carried over the other shoulder, and connected to the decarbonating or alkali chamber. The exhaled air, after passing through the alkali chamber, flows into the air reservoir, on the point of entering which it receives the required supply of oxygen, which is regulated by a small valve under the control of the wearer. The apparatus is easily carried, and has the great advantage, besides its efficiency, of leaving the limbs of the wearer free. In an able article in the *Newcastle Daily Chronicle* the moral effect of having the apparatus in readiness is pointed out, and it is believed "that a couple of the apparatus would be of more value than a score of willing explorers—in the event of a colliery explosion—with the courage, but without the means, to successfully combat the insidious effect of the after-damp."

Dr. O'Hanlon, the medical officer of the Spennymoor Local Board District, in his report, points out with regret that the use of opium is increasing in the district, and especially amongst the female population. This is much to be regretted, as the habit could not—up to late years at all events—be considered as established among our northern mining population.

Newcastle-upon-Tyne, March 24th.

EDINBURGH.

(*From our own Correspondent.*)

CLOSE OF THE WINTER SESSION.

THE winter session of the Edinburgh Medical School came to a close on Friday, the 27th ult. There was the usual interest displayed in the summing up of the work of the session by the various lecturers, and the distribution of medals and prizes to successful competitors; although, judging by the small attendance at one or two of the classes, it appeared that many students had already made their escape from college trammels to the enjoyment of a well-earned holiday. This did not interfere, however, with the lively interest displayed in the closing lecture of the class of Clinical Medicine, delivered by Professor Maclagan; for it was widely known that this was to be a valedictory address on his retirement from the chair. Long before the appointed hour the lecture theatre was crowded with students; there was also a large representation of the teachers in the Edinburgh Medical School, many of whom, now occupying important posts of responsibility, had studied under the veteran and genial professor, whom they were now assembled to honour. Professor Maclagan's entrance, supported by his colleagues of the clinical chair, was greeted with a most enthusiastic demonstration of esteem, which was warmly reiterated from time to time as some telling point, some apt illustration or classical quotation, marked the phases of his most interesting address. In a few comprehensive sentences Professor Maclagan reviewed the work done during the session, so far at least as the lectures were concerned, dealing shortly with each system of the bodily mechanism and its disorders, and pointing out the significance of each in the economy of general medicine. In the branch to which he had drawn attention specially—that of diseases of the skin—there had been no lack of interesting cases, and he congratulated the students upon the opportunity which had been afforded them of studying some of the rarer forms—as, for instance, true leprosy. Passing then to the subject of his retirement, Professor Maclagan explained that it had been for some time in contemplation, owing to the completion of the new Public Health Laboratories, to the development of which he was anxious to devote his time and energies, but that at the request of his colleagues it had been postponed until the present time. Speaking of the charm of hospital work both to the scientific physician and to the well-wisher of his fellows, he alluded feelingly to the regret which he experienced in parting from surroundings that had afforded him so many opportunities of pleasurable interest and of usefulness to others, and testified to the warm feeling of personal gratification with which he looked back upon the cordial relations which had always existed between himself and his fellow-workers, be they teachers or students. In dealing with the many phases of hospital work, he drew attention specially to the importance of children's diseases, and of the fevers, for the study of both of which increased facilities are to be provided; and, in meeting the objections which have been urged against the study of the latter, he held strongly that those whose natural bent had led them to encounter the dangers of a medical career should not flinch before an additional risk, by avoiding which they could not enter fully equipped upon the practice of their profession, and that, even here, that Providence under whose care they had prospered so far would still be their protection. Professor Maclagan then took leave of the class over which he has presided so long, his adieux receiving the most enthusiastic response from the students; and there was not one amongst them, as they rose *en masse* and waved a last farewell, but would carry away with him a kindly feeling towards the "old man eloquent," whose well-weighed words had taught him many a useful lesson, and whose gentleness and courtesy had inspired him with feelings of the deepest respect.

A WISE SCHOOL BOARD ELECTION.

The city of Edinburgh is to be congratulated upon the return of an able representative of the medical profession as a member of its newly-elected School Board. The subject of Over-pressure in Board Schools is such a burning question at the present juncture that a School Board which counts a medical man upon its roll will be viewed with much less suspicion by the parents of the oppressed infants than where this is not the case. Although returned as a "ratepayer's candidate," Dr. Russell will doubtless not feel bound to advocate that most fertile source of over-pressure, a minimising of the teachers' emoluments, that makes the straining after large grants essential to their bare existence.

DINNER TO DR. ARTHUR THOMSON.

Dr. Arthur Thomson, the newly chosen lecturer on Human Anatomy in the University of Oxford, was entertained at a congratulatory dinner by the University Assistants' Club, at the Waterloo Hotel on March 27th. Dr. Murdoch Brown occupied the chair, and amongst the guests present were Dr. Thomson, senior, Professor Turner, and Professor T. R. Fraser, Dean of the Faculty of Medicine. After the loyal and patriotic toasts had been given, the chairman proposed "The Health and Prosperity of Dr. Thomson," and paid a warm tribute to the talents as well as to the *bonhomie* which had placed him so high in the esteem of his colleagues. Dr. Thomson responded in an amusing speech. In proposing "The Assistants' Club," Professor Fraser alluded to the importance of a University being distinguished by achievements which extend the area of science as well as by the

completeness of its didactic functions, and whilst deprecating the employment of large sums for the endowment of bursaries, which reward their holders for merely doing their duty, he strongly urged that such sums should rather be devoted to defraying the expenses of scientific research, which has been largely crippled through lack of funds amongst those who might otherwise have undertaken such work with the very best results.

Dr. Arthur Thomson is succeeded in his post of Senior Demonstrator of Anatomy by Mr. David Hepburn, M.B., C.M., who has been for three years upon the staff of demonstrators.

PARIS.

(From our Paris Correspondent.)

THE DIVULGENCE OF PROFESSIONAL SECRETS.

DR. WATELET, who was fined 100 francs for having divulged a "professional secret" under circumstances referred to in my letter of March 21st, has protested by a letter in a morning paper against the judgment of the Court by refusing to sign a bulletin, a printed form which every medical man receives from the Prefecture of the Seine, and which he is required to fill up on the death of a patient. The bulletin contains as headings: name of the principal disease, final accidents, cause of death, duration of the malady, &c. Dr. Watelet appears to find this demand inconsistent with the charge brought against him, and consequently returned the bulletin unfilled to the Prefect. I am afraid, however, that he will again render himself amenable, as the name and address of the patient are written on a slip of paper which is detached from the body of the bulletin before the latter is sent back to the office of the Prefecture. As I have already observed, the position of a medical man in his relations to society is peculiarly difficult and delicate, for the construction that may be put on the article in question (378 of the French Penal Code) is so elastic that a medical man is never safe, as he may at any moment unwittingly commit himself, as in the case of Dr. Watelet. A striking example of this has just happened to another medical man in Paris. A physician, who was also a pharmacien, but who practised only in the latter capacity, lately died. Dr. Constantin Paul, in announcing the event at a meeting of the Société de Thérapeutique, of which the deceased gentleman was a member, stated that death was caused by tubercular meningitis, of which he had an attack ten years previously. The Insurance Company in which the deceased had insured his life for 200,000 francs, or £8000, having taken note of this circumstance, has refused to pay the widow, on the grounds that her husband's life was insured subsequent to the attack he had ten years before, he being at the time the subject of a fatal malady which eventually carried him off. The case, which is interesting from more than one point of view, is pending, and it is said that if the Insurance Company should persist in their refusal, Dr. Constantin Paul will be prosecuted for divulging a professional secret. Examples of this kind are daily to be met with, for we see in the medical and lay papers full descriptions of maladies of persons of note ante mortem and post mortem. At this very moment the nature of the malady from which General Grant is suffering is being publicly discussed on both sides of the Atlantic, and so was that of General Garfield and M. Gambetta, and yet no one ever dreamt of prosecuting the authors of the published articles.

THE GODARD PRIZE.

The Société de Biologie of Paris has awarded the Prix Godard (1884) to Dr. E. Leblond, for his work on the physiological and therapeutic action of caffeine.

Another election of a corresponding member of the section for Medicine and Surgery of the Paris Academy of Science, took place last week. Sir James Paget, who was elected, received thirty-eight votes, against two for Sir Joseph Lister, and one for Dr. Leudet, of Rouen. Dr. Panum, of Copenhagen, was also a candidate.

Paris, March 31st.

THE ASSOCIATION OF PUBLIC SANITARY INSPECTORS.—At the next monthly meeting of this Association, to be held April 4th (this day), at 1, Adam-street, Adelphi, at 6 P.M., an address on "Sanitation" will be delivered by Dr. B. W Richardson.

VIENNA.

(From our own Correspondent.)

GASTRO-ENTEROSTOMY.

IN removing a carcinoma of the pylorus, if too much of the stomach have to be included in the excision, the sutures—especially if of catgut—between the thick gastric wall and the thin duodenum usually relax in consequence of the great tension; for cases in which the stomach cannot be united with the duodenum, Dr. Woelfler has employed gastro-enterostomy in order to prolong the life of the patient. The stomach is united with the coils of the small intestine above the carcinoma, so that the food proceeds direct into the small intestine, eluding the pylorus and the duodenum. The method is only a palliative one, its object being to avert stenosis, as the carcinomatous masses remain behind. Professor Billroth has modified the method in the following manner. He operates like Woelfler, then he excises the stomach, lifts up the carcinoma, unites the viscus with the small intestine, loosens the carcinoma, and finally cuts it off, so that the food proceeds direct into the small intestine, and the duodenum is, so to say, an enormously lengthened ductus choledochus. A few weeks ago Professor Billroth operated in this way on a decrepit patient, who recovered satisfactorily.

DIAGNOSIS OF CARCINOMA.

Mr. E. Freund, a medical student, has described a method of diagnosing carcinoma with very few chemical aids in every stage of its development. He says there is in the blood of carcinomatous individuals a reducible substance, which he supposes to be sugar; and the blood of sarcomatous individuals contains an unusual amount of peptone. In cases of carcinoma diabetes was excluded, as was leukæmia in cases of sarcoma. In both diseases only a very small quantity of blood should be examined. In sixty-two cases of carcinoma, after the albuminous products had been removed with sesquichloride of iron and nitric acid, there was found in 0·3 cubic centimetre of blood a substance which distinctly reduced Fehling's solution. In eight cases the blood had to be heated for a few minutes with dilute muriatic acid, and glycogen, as such, could then be proved. After extirpation the sugar in the blood disappeared; in one case only it persisted, in which relapse took place. In fifteen cases of sarcoma, after the removal of the albuminous contents, peptone could distinctly be found.

TRANSFORMATION OF PUTREFACTIVE BACTERIA.

Professor Stricker recently communicated to the I. a. K. Society of Physicians the information that Professor Spina had succeeded in transforming putrefactive bacteria in the course of two days, and that they show the same behaviour towards methyl-violet as tubercle bacilli. Professor Stricker and Dr. Amrus have repeated these experiments, which corroborate Professor Spina's statements.

THE GENERAL EFFECT OF COCAINE.

In a lecture delivered recently Dr. S. Frend described some experiments he had made to illustrate the stimulating and restorative power exerted by the muriate of cocaine. The exhilarating effect of the ingestion of from 0·05 to 0·10 gramme of the drug lasts four or five hours, and disappears by degrees without being followed by depression. This effect of cocaine can be tested by the dynamometer. Under the influence of 0·10 gramme of cocaine an increase of power of pressure of the right hand of 2 to 4 kilogrammes, and of that of both hands of 3 to 6 kilogrammes, has been registered. This effect ensues shortly after the taking of the drug, and is best shown if it is taken while the system is in a condition of great depression. The daily fluctuation of the muscular strength which takes place in correspondence with the daily fluctuation of the bodily temperature, as shown by Dr. Max Bruch, is also to be taken into account in studying the effect of cocaine on the motor power.

Vienna, March 19th.

MEDICAL NOTES IN PARLIAMENT.

The Insane Poor.

IN the House of Commons on the 26th ult., Sir Charles Dilke, in reply to Mr. W. Corbet, stated that the return of poor rates and pauperism just issued does not give the total number of insane persons maintained at the public

expense. The numbers given in that return are of the pauper lunatics maintained by the guardians at the cost of the poor rates, and do not include the insane who are maintained by the counties and boroughs at the cost of the county and borough rates. The return which was prepared by the Commissioners in Lunacy and presented to the House in June, 1883, contains, so far as the Board are aware, the fullest information available on this subject.

Lunatic Asylums in Ireland.

On the 30th ult., in reply to Mr. A. O'Connor, Mr. Campbell-Bannerman said that there has not been time to ascertain the exact present condition of affairs in each lunatic asylum in Ireland, but he believed there is no doubt that in some asylums the number of patients is in excess of the nominal accommodation, although, taking the country as a whole, there is more accommodation than is actually required. The Lord Lieutenant gives immediate and full attention to any representations made to him on this subject. Several asylums have already been extended, and extensions are being or are about to be effected in others.

Sixpenny Telegrams.

Mr. Shaw-Lefevre stated that it has been decided that the new tariff shall come into force on Aug. 1st next.

Small-pox and Vaccination.

On the 31st ult., Mr. G. Russell stated, in reply to Mr. Hopwood, that the Local Government Board have no reason to doubt that the statement in the pamphlet entitled "Facts concerning Vaccination," sanctioned by his department, that "none of the nurses at any of the London small-pox hospitals who have been duly revaccinated before entering on their duties have ever caught small-pox" is substantially correct, although it might have been more guardedly expressed. From the report of the medical superintendent of the Fulham Hospital in March, 1882, it appeared that at Fulham 42 out of a staff of 295 had had small-pox, at Stockwell 16 out of 340, and at Deptford 20 out of 265.

Obituary.

REES HOPKINS, L.R.C.P., M.R.C.S.

MR. HOPKINS of Pontypridd, whose death occurred, in the forty-first year of his age, on the 1st ult., was born near Llantrissant. He commenced life as a veterinary surgeon at Pontypridd, and this vocation he pursued for some years with marked success. He afterwards commenced a course of professional study at the London Hospital, and in 1872 obtained the diplomas of Member of the Royal College of Surgeons and Licentiate of the Royal College of Physicians. He was medical officer to the Pontypridd Board of Health and the Rural Sanitary Authority, and held several other public appointments.

Medical News.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—At examinations held on March 23rd and following days, the undermentioned passed in Anatomy, Physiology, and Materia Medica:—

J. A. Coen, A. R. S. Craig, J. Duncan, J. D. O'D. Egan, R. Elliott, R. W. Hamilton, J. C. Hines, A. M. Hunt, E. B. Kennedy, A. D. Macleod, A. R. Murphy, V. Nash, H. F. C. Pilcher, J. A. Scully, A. F. Smith, P. Stephenson, W. Stritch, W. Swan, W. E. Waters, J. A. Whitty, D. T. Wylie.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on the 19th ult.:—

Mumford, Alfred Alexander, Manchester School of Medicine.

The following passed on the 26th ult.:—

Caskey, John Shaw, London Hospital.
Rhys, Watkin Llewellyn, Guy's Hospital.
Sutherland, John Russell, Glasgow University.
Walker, Thomas Greaves, London Hospital.

DR. SMYTH is a candidate for the vacant coronership of North Kildare, and it is generally expected that he will be returned.

A SUGGESTION has been offered that the "Great Eastern" steamship should be utilised as a floating hospital at Suakim.

THE salary of Dr. Cowen, medical officer of the Shadwell-road Workhouse, Islington Union, has been increased from £50 to £80 per annum.

DR. G. P. O'FARRELL of Boyle, and Dr. John Todd of Newtown Stewart, have been appointed medical inspectors under the Local Government Board, Ireland.

SPANISH UNIVERSITIES.—The number of students who graduated in the Spanish Universities last year was 3598, including 94 doctors, in various faculties, 535 licentiates in law, and 703 licentiates in medicine and pharmacy.

THE MANCHESTER HOSPITAL SUNDAY AND SATURDAY FUNDS.—The amount paid into the bank up to the present time to the credit of Hospital Sunday Fund is £4745, and on account of Hospital Saturday, £3063, making a total of £7808.

ROYAL COLLEGE OF SURGEONS.—Owing to the unprecedentedly large number of candidates for the "primary," or anatomical and physiological examination for the diploma of membership, amounting to upwards of 400, the library and museum of the College will be closed on Tuesday and Wednesday, the 7th and 8th inst.

ON Tuesday last, Mr. Alderman Walmsley, M.R.C.S., of Salford, presided at a meeting of medical practitioners of Manchester, held at the old town hall, for the purpose of taking steps to found a new Medical Society in the city. A resolution was carried pledging the meeting to promote the object in view, if possible in harmony with the existing Medical Society.

ELECTRIC LIGHT FOR HOSPITAL SHIPS.—The Metropolitan Asylums Board has contracted with a Manchester firm for lighting by means of electricity the hospital ships and buildings at Long Reach. The plant will be in duplicate throughout, and a considerable saving will be effected in the annual cost of lighting by the substitution of electricity for oil.

INFECTIOUS DISEASE HOSPITAL AT BIRKENHEAD.—On the afternoon of the 31st ult., the new ward which has been added to the hospital for the treatment of infectious diseases at the back of the Borough Hospital, Birkenhead, was formally opened by Mr. Frederick Smith, chairman of the Health Committee of the Corporation. The new ward has cost about £600.

UNIVERSITY COLLEGE HOSPITAL.—The annual general meeting of the donors, governors, and subscribers of this institution was held on the 31st ult. The number of in-patients treated during the past year was 3152, as against 2849 in 1883, and of out-patients 33,743, as compared with 24,187. The annual subscriptions amounted to £2047, and the total reliable income to a little over £6000, whilst the necessary annual expenditure reaches £19,000.

THE ROYAL COMMISSION ON THE HOUSING OF THE POOR.—It is stated that arrangements have now been completed for the visit of the Royal Commission on the Housing of the Poor to Scotland. The visit is not one of inspection, but simply for the taking of evidence. The Commission will sit this day (Saturday), Monday, Tuesday, and Wednesday, and possibly for a few days longer. The Commission will probably visit Dublin during the Whitsuntide recess.

LOWER THAMES VALLEY DRAINAGE.—The Local Government Board have addressed to the clerks of several constituent authorities comprised in the Lower Thames Valley Main Sewerage Board a letter, dated March 26th, stating the decision of the Local Government Board, after careful consideration of the report of their inspector (Mr. J. Thornhill Harrison, C.E.), on the recent inquiry held by him as to the proposal that certain of the districts now included in the Lower Thames Valley Main Sewerage Board should be separated from that district. The letter deals first with the application of the Heston and Isleworth Local Board, and states that the Board have determined, if the Local Board, after further consideration of the matter desire it, to issue a provisional order separating the districts of Heston and Isleworth from the main sewerage district. With regard to the separation of other districts as to which opposition was made, the Board are not prepared to issue a pro-

visional order for the dissolution of the main sewerage district, or the separation of any constituent portion, with the exception of the two above-named districts. The letter also states that the Local Government Board are of opinion that before the Joint Board arrive at a final decision with regard to Sir J. Bazalgette's scheme (which, in the event of its adoption, should be carefully revised and perfected before it is submitted to the Board) they should fully consider whether it might not be practicable to adopt some other scheme which would provide for the disposal of the sewage outside the district of the Joint Board, and which would entail less cost.

PRIZE SUBJECTS IN BARCELONA.—The following subjects have been chosen by the Royal Academy of Medicine and Surgery of Barcelona, for the annual prize dissertations this year:—1. Description of an Epidemic in Spain. 2. Best Method of preparing Cocaine. 3. Medical Topography of some District in Spain. 4. History and Present State of Hygienic Education in Spain.

PRESENTATION.—On January 17th last a testimonial of 1000 rupees, which had been subscribed by the tea-planters and other residents of Kursung and the Terai (Bengal), with an address, was presented to Dr. A. B. Morris, who for the last ten years has practised as "planters' doctor" in that place, but the state of whose health is such that a change to a colder climate is considered necessary. Dr. Morris has gone to Auckland, New Zealand, where he hopes to found a practice.

OXFORD WATER-SUPPLY.—The informal committee appointed in June last to investigate this subject has submitted several samples to the analysis of Dr. Frankland and Dr. Tidy. Their reports were on the whole not unfavourable, but the water company has made the proposal to draw its supply from the Thames at King's Weir, some three miles above Oxford; and this plan, according to Professor Prestwich, seems to offer, apart from the question of cost, the best and most abundant supply of river water. He thinks "that with water drawn from this source, with proper settling reservoirs, and with the efficient filtering reservoirs now in course of construction, the water-supply of Oxford would in the future be as good and as abundant as could be ordinarily obtained from a river source, and that there would be little risk of a recurrence of those conditions to which there has been at times so much reason to object."

ROYAL COLLEGE OF SURGEONS IN IRELAND.—MEDICAL SCHOOL.—The following prizes have been awarded at the termination of the winter session 1884-85:—Descriptive Anatomy: Senior Medal, Mr. Powell; First Class Certificates, Messrs. Bewley, Cummings, Strangman, and Nelson; Second Class Certificates, Messrs. Barter, Beamish, Ferguson, and Gourley. Practical Anatomy: Senior Medal, J. Lagan; First Class Certificates, Messrs. Matthews, Fenton, Hickey, O'Donohoe, Reid, Rossiter, Strangman, C. Woodwright, W. Woodwright, and Cook. Descriptive Anatomy: Junior Medals, Messrs. Gore and Johnston; First Class Certificates, Messrs. Banks, Ewing, Summers, and Jennings; Second Class Certificates, Messrs. Bruland, Lyons, Green, Molloy, McMunn, Clarke, Stewart, Harding, Finnegan, and Lee. Practical Anatomy: Junior Medals, Messrs. Byrne and Gourley; First Class Certificates, Messrs. Gore, Johnston, Marwood, Beamish, Cummings, O'Rafferty, Nelson, Lyons, Hanks, Barter, and Cremin.

SOCIETY FOR THE STUDY AND CURE OF INEBRIETY.—The annual meeting of this Society will be held on Tuesday afternoon, the 7th inst., in the rooms of the Medical Society, Chandos-street, W., at four o'clock, when, after an address by the President, Dr. Norman Kerr, a paper will be read by Dr. T. D. Crother, Hartford, on "The Incipient Stages of Inebriety." The following have been elected officers for the year:—President: Dr. Norman Kerr. Vice-presidents: Sirs G. Burrows, W. Miller, G. H. Porter, E. Saunders, and Spencer Wells; Professors B. Foster, Macalister, McKendrick, and Maclagan; Surgeon-General Logie; Drs. J. S. Bristowe, Cameron, M.P., W. B. Carpenter, Farquharson, M.P., C. J. Hare, Geo. Harley, Wm. Ogle, B. W. Richardson, W. H. Walshe, and C. J. Wheelhouse. Treasurer: Dr. Drysdale. Hon. Secretary: Dr. Sturrock. Council: Surgeon-General C. R. Francis; Surgeons-Major Evatt and G. K. Roole; Drs. Balding, Barnes, Beverley, Bridgewater, Alfred Carpenter, J. Eastwood, Fitch, Gibson, Haynes, Hicks, Hurry, Lindsay, Reddie, Robertson, and Thomas.

THE PREMONITORY SYMPTOMS OF INSANITY.—Dr. Henry Sutherland read a paper on the above subject at Brighton on March 24th, at the meeting of the South-Eastern Branch of the British Medical Association. In this paper it was shown by cases which had been for a long time under observation, that various eccentric acts sometimes occur many (seven, twelve, fourteen) years before the actual outbreak of insanity takes place. Hence the necessity for early prophylactic treatment in cases where the insane temperament is strongly marked. The mental and bodily symptoms usually noticed in the early stages, and the indications for various drugs, were also enumerated. The importance of appropriate moral and hygienic treatment was also insisted on. By attention to these details a second attack was often averted, and if insanity had actually seized the patient, the duration of the disorder was shorter and the outlook more hopeful than would have been the case had treatment been neglected.

Medical Appointments.

Intimations for this column must be sent DIRECT *to the Office of* THE LANCET *before 9 o'clock on Thursday Morning at the latest.*

DAVIES, SIDNEY, M.A., M.B.Oxon., M.R.C.S. (of Cairo), has been appointed Médecin en Chef de la Police et de la Gendarmerie Egyptienne.

DENDY, WALTER C., F.R.C.S.Eng., L.R.C.P., has been appointed Assistant Medical Officer to the Workhouse of Birmingham Parish, vice Williams, resigned.

FRASER, JAMES A., L.R.C.P.Lond., M.R.C.S., has been appointed Medical Officer to the Workhouse of the Romford Union, vice Davey, resigned.

GARNER, JOHN EDWARD, M.D., C.M.Aber., has been reappointed Medical Officer for the First District of the Preston Union.

MCCRACKEN, JOHN, M.B., C.M.Glas., has been appointed Medical Officer for the Coxwold District of the Easingwold Union, vice Steven, resigned.

MATHESON, FARQUHAR, M.B., C.M.Aber., has been appointed Honorary Aurist to the Royal Caledonian Asylum.

MURRAY, H. MONTAGUE, M.D., M.R.C.P., has been elected Honorary Physician to the Foundling Hospital, vice Dr. A. Tweedie, deceased.

SMITH, HENRY LIONEL, L.K.Q.C.P.I., L.R.C.S.I., has been appointed Medical Officer for the Overburg District of the Tewkesbury Union, vice Heslop, resigned.

Births, Marriages, and Deaths.

BIRTHS.

BUZZARD.—On the 26th ult., at Grosvenor-street, W., the wife of Thomas Buzzard, M.D., of a daughter.

FLECK.—On the 27th ult., at Frogmoor Lodge, High Wycombe, Bucks, the wife of William Fleck, M.D., of a daughter.

HETT.—On the 27th ult., at Inverness-terrace, the wife of Geoffry Hett, M.D., of a son.

HOYSTED.—On the 31st ult., at 17, The Avenue, Colchester, the wife of John Hoysted, Surgeon, Medical Staff, of a daughter.

PEDLEY.—On the 22nd ult., at 25, Burnley-road, Stockwell, S.W., the wife of R. Denison Pedley, L.D.S., M.R.C.S.Eng., of a daughter.

STAMPER.—On the 28th ult., at Pembroke Dock, the wife of J. Fenton Stamper, M.D., of a son.

MARRIAGES.

HARRISSON—FREEBORN.—On the 25th ult., at St. Mark's, Kennington, John W. Harrisson, M.B., of The Friars, Sandwich, to Charlotte E. Freeborn, second daughter of the late Dr. R. Fernandez Freeborn of Oxford.

WHITELEGGE—HORSLEY.—On the 23rd ult., at St. Margaret's, Westminster, Benjamin Arthur Whitelegge, M.D., to Fanny Marian, elder daughter of J. C. Horsley, Esq., R.A., of High-row, Kensington.

DEATHS.

BRIDGMAN.—On the 19th ult., at Berkeley, Gloucestershire, suddenly, Isaac Thomas Bridgman, Surgeon, aged 43.

HASTINGS.—On the 25th ult., at Mansfield-street, Portland-place, Cecil William Hastings, M.D., in his 56th year.

PEARSE.—On the 28th ult., at Godfrey House, Cheltenham, George Pearse, M.D., late Director-General, Madras Medical Department, and Honorary Physician to Her Majesty, aged 88.

STEIL.—On the 25th ult., suddenly, at 110, Shepherd's-bush-road, West Kensington-park, W., George Robert Steil, L.R.C.P., M.R.C.S., youngest son of James Steil, Esq., R.N., in his 35th year.

N.B.—*A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.*

Medical Diary for the ensuing Week.

Monday, April 6.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10.30 A.M., and each day at the same hour.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M., and each day at the same hour.

ST. MARK'S HOSPITAL.—Operations, 2 P.M., and on Tuesdays at the same hour.

HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.

METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.

ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.

ROYAL INSTITUTION.—5 P.M. General Monthly Meeting.

Tuesday, April 7.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at the same hour. Ophthalmic Operations on Mondays at 1.30 and Thursdays at 2 P.M.

ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.

CANCER HOSPITAL, BROMPTON.—Operations, 2.30 P.M.; Saturday, 2.30 P.M.

WESTMINSTER HOSPITAL.—Operations, 2 P.M.

WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.

PATHOLOGICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Dickinson: Violet Pigment discharged from the Mouth.—Dr. Carrington: Atrophy of the Liver.—Dr. Charlewood Turner: (1) Rupture of the Aorta; (2) Ulceration of Aortic Valves and Aorta (card); (3) Aneurysm of Splenic Artery (card).—Dr. Parry Price: Deposit of Bone in Testis and Epididymis.—Dr. Colcott Fox: Thrombosis of the Vena Cava, &c.—Dr. Norman Moore: (1) Cavity in the Lung of an Infant; (2) Renal Disease in an Ox (card).—Dr. Silcock: Congenital Sarcoma of Testis.—Mr. R. W. Parker: Congenital Sarcoma of Testis (card).—Dr. Chaffey: (1) Early Sarcoma of Testis (card); (2) Congenital Malformation of the Pulmonary Veins (card); (3) Congenital Malformation of the Heart (card).—Dr. Ernest Clarke: Congenital Malformation of the Heart (card).

Wednesday, April 8.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.

MIDDLESEX HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.—Ophthalmic Operations on Tuesdays and Thursdays at 1.30 P.M.

ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Skin Department: 9.30 A.M., on Tuesdays and Fridays.

ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.

LONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.

GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Saturday, 2 P.M. Skin Department: 1.45 P.M.; Saturday, 9.15 A.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 3 to 4 P.M.

ROYAL MICROSCOPICAL SOCIETY.—8 P.M. Dr. C. T. Hudson: New Floscules.—Dr. J. D. Cox: Structure of the Diatom Shell; Siliceous Films too thin to show a Broken Edge.—Mr. H. Mills: Filamentous Projections of Diatoms.—Exhibition of Nobert's Diamonds.

BRITISH GYNÆCOLOGICAL SOCIETY.—8.30 P.M. Specimens will be shown by Dr. Fancourt Barnes, Mr. Lawson Tait, Mr. Reeves, and others.—Dr. Aveling: A Case of Double Pyo-salpinx.—Mr. Lawson Tait: A Case of Pyo-salpinx.—Dr. Bantock: A Case of Hydro-salpinx.—Dr. Lamprey: A Case of Double Monstrosity.

Thursday, April 9.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Surgical Consultations, 1.30 P.M.

CHARING-CROSS HOSPITAL.—Operations, 2 P.M.

NORTH-WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

Friday, April 10.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1.30 P.M.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—8 P.M. Mr. Percy Dunn will show Calvarium from Hernia Cerebri after Trephining, in a Child; Splenic Infarct from Pyæmia; Secondary Scirrhus of Posterior Wall of Left Auricle.—Mr. C. B. Keetley: Two Cases of Osteotomy of the Hip; Radical Cure of Umbilical Hernia.—Mr. S. Benton: A Successful Case of Colotomy.—Mr. C. W. Chapman: A Case of Suppurating Cyst of the Liver (probably hydatid); recovery.—Mr. E. Noble Smith: Illustrations of some Orthopædic Cases.—Mr. T. Pickering Pick: Subcutaneous Division of Sphincter Ani.

CLINICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Lewis Marshall (Nottingham): Cases of Amputation at the Hip-joint by Furneaux Jordan's Method.—Mr. Jonathan Hutchinson: Amputation at the Hip-joint in certain Desperate Cases.—Dr. Colcott Fox: Pityriasis Circinè (Hovand) and Pityriasis Circinè Marginé (Vidal).—Dr. Sidney Phillips: A Case of Sporadic Cretinism (living specimen).—Mr. Strugnell: A Case of Complete Paralysis of the Right Fifth Nerve.

Saturday, April 11.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editor."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe, or recommend practitioners.

Local papers containing reports or news-paragraphs should be marked.

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

SPONTANEOUS EVOLUTION.

To the Editor of THE LANCET.

SIR,—The following case, which occurred at Guy's Hospital, is, I think, worth recording, as there are several points of interest in connexion with it.

C. H——, aged forty-three years, eleventh confinement. Labour commenced at 11 P.M. on the 8th. The extern was sent for, and on arrival found that the breech was presenting in the first position. Labour progressed rapidly, and the child was born alive at 11.40 P.M. It was then found that there was a second child in utero, but the presentation was not made out. At 12 P.M. (twenty minutes after the birth of the first child), the pains being absent, a drachm of the liquid extract of ergot was administered. The pains came on rapidly, and the right hand of the child was extended through the os. On this the extern sent for me. On arrival, I found that the child was born, the hand having descended still further, until both it and part of the forearm were outside the vulva. The pains now increased in severity. The right side and buttock of the child were born next, the right hand and forearm remaining outside the vulva; the head followed shortly afterwards, the left hand being extended over it. Artificial respiration was employed for about twelve minutes before the child breathed. Both were female children, the last born being exceedingly small.

In cases of spontaneous evolution like the foregoing it is extremely rare to find the child born alive. In this case several circumstances were favourable. (1) The first child had already enlarged the passages; (2) the woman had had ten children before; (3) the small size of the child. I weighed the child a month later, when it turned the scale at 3 lb. 12 oz.—Believe me, Sir, your obedient servant,

C. Y. SHUTER, M.B.,
March 16th, 1885. Resident Obstetric, Guy's Hospital.

Dr. A. Harkin (Belfast).—Our correspondent will find a full account of the subject in the Comptes Rendus de la Société de Biologie, published by M. G. Masson, 120, Boulevard St. Germain, Paris.

Kentigern will no doubt obtain the information he desires from the registrar of the College.

EFFECTS OF HANDLING DYNAMITE.

To the Editor of THE LANCET.

SIR,—I shall be glad if any information can be given how to avoid the unpleasant consequences of handling dynamite. Two officers of the Royal Engineers employed on the fortifications here have both complained of a bad headache lasting for about twenty-four hours after handling this substance, and also sore eyes. One of them made use of gloves, but a headache still resulted, apparently from the smell. I was not aware that nitro-glycerine acted through the medium of the skin or atmosphere, and no mention of this is made in Ringer's Therapeutics. I am, Sir, yours truly,

Aden, March 18th, 1885. E. COLSON, Surgeon-Major.

DR. CHANDELON'S PROCESS FOR DETECTING STRYCHNINE.

By this method the objects to be tested are chopped up very fine, and are mixed with an equal weight of gypsum entirely freed from water. After drying, the whole is pulverised, and thoroughly boiled with 90 per cent. alcohol, to which a little tartaric acid has been added. The alcohol is removed by distillation after filtration, the residue being taken up with boiling water, filtered so as to remove all fat, compressed to 1½ to 1¾ cubic inch, and mixed with gypsum. After stiffening and pulverising, the mass is treated with chloroform in Soxhlet's apparatus. The chloroform extract is brought to ½ or 1 cubic inch, and there is added an equal volume of a saturated solution of oxalic acid in ether. The oxalate of strychnine becomes crystallised in needle-shaped forms, from which the strychnine can be isolated by ammonia. This method is said to have been successful in detecting minute quantities of strychnine, and to be likewise applicable to tests for brucine, narceine, papaverine, thebaine, aconitine, atropine, hyoscyamine, veratrine, nicotine, and coniine.

Mr. T. A. Buck, M.B.—We must refer our correspondent to some remarks on the subject in our issue of Sept. 27th, 1884.

"THE PHARMACY OF COCAINE."

To the Editor of THE LANCET.

SIR,—In an annotation on this subject in your issue of March 14th attention is drawn to a method for the preservation of solutions of cocaine by means of filtration through animal charcoal and subsequent addition of salicylic acid. I would point out to those who adopt this method the fact that animal charcoal removes alkaloid as well as impurities, and that filtration through this medium is calculated to seriously weaken the strength of cocaine solutions, especially those containing the smaller percentages of the salt. The preservation of these solutions is well effected by the use of salicylic acid alone, as recommended by Dr. Squibb of Brooklyn, employing a saturated solution of the acid in distilled water, to the extent of 50 per cent., or one-half, of the finished solution of cocaine—i.e., one-half water, and the other half solution of salicylic acid. The proportion of salicylic acid contained in the whole is then about 1 in 600, a quantity quite unobjectionable in use, but sufficient for the purposes of preservation. The alleged objection to its use on account of its extreme sensitiveness to traces of iron, and consequent difficulty in obtaining colourless solutions, we have not found realised in practice. We find no difficulty in sending out colourless solutions thus protected. The cocaine salts of our manufacture are not allowed to come in contact with iron at any stage of the process, glass and porcelain being alone employed. It was well pointed out by Mr. Symes in your issue of March 21st that an excess of acid destroys or renders latent the anæsthetic power of cocaine salts, as, so far as we are aware, this important fact had escaped record, although probably not observation. The addition of an acid to effect solution of the cocaine salt is entirely unnecessary if the neutral hydrochlorate be used. The alkaloid itself would be the most powerful, but its slight solubility (1 in about 700) almost precludes its use, although even in this high state of dilution it still has the characteristic benumbing effect on the tongue. The most important impurity in cocaine salts observed up to the present is the supposed inert alkaloid hygrine which exists in the leaves in variable proportion, and which, being considerably more soluble in water than cocaine, can be readily separated by prolonged washing and repeated reprecipitation of the cocaine, a process which also causes considerable diminution in the field of the latter, if means are not adopted for its subsequent recovery from the washings. Tests for the identification and purity of cocaine salts are greatly needed at the present time. For the first we know of no chemical tests available for the purpose. Its reactions are similar to those of other alkaloids; its anæsthetic effect on the tongue and other mucous surfaces is, however, sufficient for its identification. But this test is no guarantee of its purity; a small admixture of cocaine with other substances would produce its characteristic effect. Perhaps the most satisfactory test of purity is the amount of alkaloid precipitated by means of a solution of sodic carbonate from a weighed quantity of the cocaine salt. In the case of the neutral hydrochlorate this should amount, when moderately washed and dried until the weight is constant, to at least 89 per cent.

We are, Sir, yours faithfully,

High Cross, Tottenham, March 25th, 1885. TANNER & Co.

Mr. Hamilton Cartwright.—Would it not be better to bring the matter under the notice of the College of Surgeons?

Mr. Gem.—The report will appear in an early number.

"APPLICATION OF MIDWIFERY FORCEPS."

To the Editor of THE LANCET.

SIR,—As many letters have appeared in your journal on this subject, there is yet another method—namely, "with the patient directly on the back." This position obviates the necessity for drawing the patient over the edge of the bed, and can be more easily employed where the bedding is on the floor, as may occasionally be the case. In a manual on midwifery which has recently reached its fourth edition there is no allusion to this position. The manipulation of the superior blade is similar to the manner described by Mr. Lucas. As everybody appears to be conversant with Mr. Lucas's easy method, I would give him the satisfaction of knowing that it is new to me. I am, Sir, yours truly,

March 14th, 1885. BRAVER.

DISCOUNT IN DRUG BILLS.

A PETITION has been presented to the College of Pharmacists of Madrid praying that any members who may be guilty of selling drugs to corporations, societies, or charitable establishments at any considerable reduction from the recognised price may be expelled. The Madrid medical journal which reports this thinks that if it is carried into effect the College will have to expel a large number of its members—in fact, nearly all those who happen to supply public institutions.

A Country Doctor.—Our correspondent seems entirely right. But we still think his case would be more complete with some personal remonstrance, preferably an interview.

M.B.Lond.—The letter has been already published in a contemporary.

FLOATING DISPENSARIES FOR FISHERMEN.

To the Editor of THE LANCET.

SIR,—Through the kindness of a gentleman much interested in the North Sea Fishing Fleets, I had an opportunity last August of spending a fortnight on board one of the mission ships belonging to the Mission to Deep Sea Fishermen. What I then witnessed has induced me to bring the subject before the medical profession, in the hope that they will lend their aid towards alleviating the sufferings which smacksmen have to undergo, owing to the inefficient supply of medicines and medical appliances available in cases of illness. During the entire year a floating population of over 12,000 men and boys are at work in the North Sea, trawling for the fish with which Billingsgate and other markets are supplied. This great fleet is divided into eight minor fleets, each under the command of an "admiral," a sailor selected for his long experience and thorough technical knowledge, who, by means of day signals by day and rockets at night, indicates the direction in which the boats should sail, and the times for lowering and hauling up the trawls. The nature of the occupation in which these sailors are engaged is both some, harassing, and dangerous in the extreme. For eight weeks continuously each trawler is at work, a period of nine days being then allowed the crew to return home to recruit themselves and refit their smacks. Sailing with this fleet are some vessels which, besides engaging in trawling as the other vessels, are used as mission ships, and which also act as floating dispensaries. Being only four in number, they attach themselves to four of the minor fleets. A medicine chest (which has been pronounced by one of the sailors to be "one of the greatest blessings in the fleet") is kept on board each of these ships; but the natural want of knowledge on the part of the skippers, combined with the extreme difficulty of dispensing small doses of powerful medicines on board a small craft in heavy seas, greatly diminishes the advantage to be derived from such a provision. Under these circumstances, I propose to furnish one of the fleets with a supply of concentrated medicines, such as are found most generally useful in dispensary practice, directions being given on each bottle as to the complaints for which such medicine is to be employed. Further, to supply a number of empty graduated eight-ounce bottles, so that, the doses being marked, the use of spoons (which for obvious reasons would be useless) can be dispensed with. The concentration of the medicine being uniform (one drachm to the ounce), the only dispensing necessary would be to take one of these empty bottles and a sufficiency of the concentrated mixture to fill a graduated ounce space, and then fill the bottle with water, directing the patient to take a marked dose three or four times a day, according to the urgency of the case, thus obviating the use of measure glasses, table- or dessert-spoon, or other superfluities unknown on board a trawler. After thus providing for one fleet, seven others remain in need of some such provision. I would therefore earnestly appeal to the members of the profession, in the hope that they will contribute towards this object by either becoming responsible for the supply of medicines to some of the fleets, or by sending to the Secretary of the Mission to Deep Sea Fishermen—E. J. Mather, Esq., 31, New Bridge-street, Ludgate-circus, E.C.—contributions towards providing for the expenses of such.

May I express a hope that through the columns of your journal you will aid the project by giving to it that publicity which it merits, and thus eliciting aid, as well as suggestions, as to the best manner of working the system. An early expression of the views of the profession would much oblige, as I am making arrangements for again visiting the fleet at an early date.—I am, Sir, yours faithfully,

HENRY J. PENNY, L.R.C.S., L.K. & Q.C.P.I.

Shenley, Barnet, Herts.

A TITLE FOR APOTHECARIES.

To the Editor of THE LANCET.

SIR,—Having observed your reply to "L.S.A." in last week's LANCET, in which you stated that the titles of "Doctor" and "Surgeon-Accoucheur" were, though not illegal, not "warranted" by the holders of the licence of the Apothecaries' Society, might I ask the favour of an opinion from you upon the following:—I am in the habit of describing myself, with the same qualification, as "Licentiate in Medicine." I cannot call myself "Apothecary," as I practise with the full sanction of the law as a physician, and I think it to a certain extent immoral to describe myself as "Doctor" and "Surgeon-Accoucheur." It appears to me and my friends an excellent and honourable way out of the difficulty.

I am, Sir, your obedient servant,

March 28th, 1885. LICENSED IN MEDICINE.

*** We see no objection to the description our correspondent gives of his qualification.—ED. L.

D. writes: "I shall be grateful if any of my professional brethren will advise me what is best to do (educationally) with a youth, aged thirteen, not idiotic, but yet of such defective mental capacity that it would be out of the question to send him to any ordinary school. He is not more difficult to control than such cases usually are. He is the only child of a widow with very limited means."

RAPID SPONTANEOUS RESOLUTION OF A DEPRESSED FRACTURE OF THE PARIETAL BONE.

To the Editor of THE LANCET.

SIR,—The following case may prove interesting to some of your readers.

At 3 P.M. on the 4th inst. A. P——, a child one year old, was brought to me, having fallen from its nurse's arms. The mother told me that at the time of the accident the child became semi-convulsed, and livid for a few minutes, but did not lose consciousness. When I first saw it, fifty minutes after the accident, it was perfectly sensible, and apparently in its usual condition. On examination, the skin was normal; there was no bruising or swelling, but an indentation, an inch long, two-thirds of an inch broad, and one-third of an inch at its deepest part, occupied the position of the left parietal eminence. With the exception of a little tenderness on manipulation of the part, the child was in no way inconvenienced, and so little was the disturbance, that I remarked the depression, that I at once put it down to a malformation previously existing, but only now discovered and attributed to the accident. The mother, however, assured me that such was not the case, and she was duly dismissed with the necessary instructions as to the treatment of the child. On the next morning I saw the child; it was doing well, and without a trace of the accident of the previous day. The mother informed me that she had noticed that by 7 P.M. on the day of the mishap the skull had resumed its normal appearance. The case seems to me to be remarkable in the following points:—1. The slightness of the shock and the rapid recovery from it, and the immunity from symptoms co-existing with such a state of affairs. 2. The situation and character of the depression; its taking place at the strongest and most thoroughly ossified part of the bone, this being completely inverted, to apparently greater extent than it was formerly convex, and this without any evidence of detachment or crepitation. 3. The rapidity of duration—i.e., four hours—showing the pliant nature of the bone, more especially of the inner table of it, at this age, and the force exerted by the blood pressure, and the rhythmical pulsation of the brain.

I am, Sir, yours truly,

Kettering, March 16th, 1885. JOHN GRANT, M.B., C.M. Edin.

PERMANGANATE OF POTASH IN AMENORRHŒA.

To the Editor of THE LANCET.

SIR,—I reported a case of amenorrhœa successfully treated with permanganate of potash pills in THE LANCET of Jan. 24th, 1885. Since then another case has been brought to a successful issue by the same treatment. M. C——, aged eighteen years, came under my care on Feb. 1st. The patient was by occupation a dressmaker in Dublin, where she had been under medical care for some time; but her health did not improve, and she returned home and consulted me for the following:—Short cough; pain in the cardiac region and in the small of the back; pulse 100 and weak; tongue and gums anæmic; appetite bad; blowing, systolic murmur; and amenorrhœa, that had lasted for two months. I at once ordered her a tonic of iron, strychnine, and quinine, with plenty of nourishment, and at the end of a week, when her general health was greatly improved, I ordered permanganate of potash pills, one grain each, one pill to be taken with each meal. Six of these pills produced the desired effect, and the catamenia appeared in a similar manner four weeks afterwards. She is now taking a course of iron pills. The murmur has vanished, and she is going on in a most satisfactory way. I remain, Sir, faithfully yours,

CHARLES F. MURRAY, M.D.

Ashfield, Beau Pare, co. Meath, March 28th, 1885.

Cumbriensis.—The Local Government Board may, upon the application of the sanitary authority, dispense with so much of the regulation required in its circular as requires that the medical officer of health, being duly registered, shall be qualified to practise both medicine and surgery.

"HYDROCHLORATE OF COCAINE."

To the Editor of THE LANCET.

SIR,—It matters little to your readers whether Mr. Fenwick or Mr. Tebbett suggested camphor water as a menstruum in which to preserve the hydrochlorate of cocaine as a solution. The credit, however, belongs to the latter (THE LANCET, Feb. 14th, p. 315). My object in writing was to offer testimony to the value of such a solution, and to caution the profession against trusting to Mr. Churchyard's assumption that a solution in distilled water which had become flocculent could be rendered as active as when freshly prepared by the treatment he mentioned. It is well known that a solution of cocaine hydrochlorate is rendered weaker by being passed through animal charcoal, and, as I have stated, the addition of acid further reduces its activity. A 4 per cent. solution which has become flocculent may still possess some activity, and this is best obtained by passing it through a small piece of good filtering paper and adding a fragment of camphor to the filtrate.

I am, Sir, yours faithfully,

Liverpool, March 28th, 1885. CHARLES SYMES.

MEASLES IN GUERNSEY.

A CORRESPONDENT informs us that an epidemic of measles in Guernsey has been made the subject of a paper in the *Glasgow Medical Journal* by one of the medical men there. This paper, it is alleged, has been printed separately, and sent by its author to one of the patients of another medical man holding a high official position in the island. It is an essential part of our correspondent's communication that the epidemic was of an ordinary kind, characterised by no unusual complications calling for comment, and that the mortality was small. Our opinion is asked as to the action of the author in distributing his paper to the patients of other medical men. We think that such a use of professional writing is better avoided.

PALATABLE PREDIGESTED FOOD.

To the Editor of THE LANCET.

SIR,—In the leader upon Diet in the Febrile State in your issue of March 21st, alluding to the use of "already partially digested foods" for the purpose of avoiding the "fermentative changes from delayed intestinal digestion," you say that "unfortunately the preparations hitherto proposed for this purpose do not combine palatableness with efficiency," further expressing the opinion that an improvement in the former of the conditions named is much to be desired. Seeing what weight of authority every utterance of yours has, it were to be wished you had qualified the statement by the words "some" or "most of"; since I can bear testimony (unsolicited, I need not say, and without interest) that one firm of chemists at least has solved the problem of making an efficient article agreeable in smell and taste as well. Everyone knows how seldom in our homes and sick-rooms, at the hands of our cooks or nurses, we ever get a really good cup of coffee or cocoa; and I am quite sure that, the prejudice of a first trial once over, the almost instantly prepared cup of peptonised cocoa and milk or coffee and milk would be preferred as richer and more delicate in flavour to what we usually have placed before us. And if a preparation is really nicer to a healthy palate, efficiency being ensured, how much fitter must it be for the fastidious or perverted taste of the sick? I have for some time made use of the above preparations in typhoid fever, in tubercular affections of the abdominal organs, in acute and chronic albuminuria, and in diabetes mellitus, as well as in varying degrees of gastric irritation—in brief, in a wide range of cases where impaired digestion was only a secondary or even hardly appreciable factor, and in all with more or less benefit. In one case of diabetes, carefully watched for a month, and the urine daily examined, somewhat (I admit) to my surprise, the administration morning and evening of one breakfast-cup of the peptonised cocoa and milk did not increase the excretion of sugar; all the other conditions being as nearly as possible alike during that period, the gluten loaf not being used, and the only drugs administered being salicylic acid with a quarter of a grain of codeia.

I am, Sir, yours truly,

March 25th, 1885. F. ARNOLD LEES, M.R.C.S. &c.

*** Both cocoa and coffee undoubtedly disguise the peculiar flavour of peptonised food better than anything else; still, even thus prepared, peptonised preparations have, to our taste, in a slight degree the peculiar flavour, which to some persons is extremely unpleasant, of peptones, though in this respect they are superior to most dietetic articles of this kind.—ED. L.

M.R.C.S.—We do not think it advisable to extend to such cases further publicity. The attention of the bodies whose qualifications the offenders hold should be called to the way in which their diplomas are disparaged.

"CARBOLIC OIL A REMEDY AGAINST MOSQUITOES."

To the Editor of THE LANCET.

SIR,—The unfortunately too frequent differences amongst doctors when they do ventilate their opinions may, so far as the above matter is concerned, be very easily explained. The application of carbolic acid and oil, in the proportion of 1 to 10 or 15, is for a time perfectly successful in keeping off mosquitoes; but the carbolic acid evaporates so rapidly that a renewal has to be made every half-hour or thereabouts. So far as my experience goes, there is no place where the sting of the mosquito is so venomous as on the banks of rivers and lakes, and after exposure in such places I have known men to be laid up and disfigured for weeks. By using the oil, and repeating its use every half hour or so, I have fished where all other fishers were half smothered with mosquito muslin wrapped round them—and in the tropics this is very heat-producing, even if effectual in keeping out the "wily mosquito"—with perfect impunity, and the only difficulty I had was to keep it out of my eyes, as it produces smart pain if it touches the conjunctiva. Put a bottle of freshly mixed acid and oil in your pocket, and apply it at frequent intervals on hands, neck, and face, and you may defy mosquitoes, gnats, *et hoc genus omne*. My experience includes the East and West coasts of Africa, the East and West Indies, North America, and the Arctic. The Arctic black gnat in summer is as annoying as any "punkah mosquito." Before I used carbolic oil I employed creasote and oil, and a mixture of it used to be sold at least a quarter of a century ago by the fishing tackle folk in the land of the "Blue Noses;" indeed, it was my experience there which led me to substitute the carbolic acid for the creasote. I am, Sir, yours faithfully,

March 28th, 1885. AN OLD SALT.

HOMES FOR MENTAL CONVALESCENTS.

To the Editor of THE LANCET.

SIR,—Amongst the many valuable institutions of the day is there not one greatly needed—convalescent homes for our pauper lunatic asylums? All medical men who superintend these asylums would, I believe, agree on the value of such convalescent homes, not only as preparing patients for return home when rallying, but as more likely to lead to recovery than at present is the case. And what a boon the change would be to those whose nervous system has been shattered!

"The very air, the sun, the skies,
Would seem like opening paradise."

And for those preparing for return to cottage homes, &c., would not a large farmhouse or some such home, with simplest furniture, but with possibly garden and poultry, be sufficient, and better than grander buildings? Such convalescent homes might be attainable without great outlay, as the patients would still be paid for, as at the asylums?

I am, Sir, yours faithfully,

March 30th, 1885. H. B.

*** Our correspondent will find, on referring to our issue of May 17th, 1884, a letter from the Rev. H. Hawkins, Chaplain of Colney Hatch Asylum, calling attention to the want of convalescent homes "to supplement the recovery of patients discharged from asylums for the insane." As we then pointed out, the need of such institutions has long been recognised.—ED. L.

TWIN BIRTH IN WHICH ONE CHILD WAS AN ANENCEPHALUS.

To the Editor of THE LANCET.

SIR,—On March 15th I delivered Mrs. B——, in her sixth confinement, of a living female child, and on perceiving two cords I examined, expecting to find a normal vertex presenting, as in the first case, instead of which I felt the cranial bones loosely covered with skin. Uterine action setting in, a fœtus was expelled, smaller than the first, perfectly developed as regards bodily conformation apparently. On section of the scalp not a vestige of brain tissue was to be seen, merely the membranes thickened and congested. The husband informed me that his wife received a severe shock seven months since at the sea-side, when she saw a hideous-looking man, and he states that the physiognomy of the encephalon corresponded exactly with the individual she then saw, it having the same depressed bridge of nose, &c. I should add that there was only one placenta. I am, Sir, yours faithfully,

Hollywood-road, S.W., March 24th, 1885. WM. J. HEDDY, M.R.C.S.

Mr. C. C. Burman (Belford, Northumberland).—The inquiries addressed to us are matters requiring careful investigation. We have found the paroxysms to be almost always more frequent at night, whether the patient sleep or not. In the early part of the course of the complaint the paroxysms frequently occur when the child is put to bed and at about 2 or 3 A.M. Profound or light sleep, in our experience, exercises but little influence; when sound sleep is possible, the attack is generally slight. Any striking alterations in the patient's environment may induce an attack.

PAIN IN THE FOOT AFTER HEMIPLEGIA.

To the Editor of THE LANCET.

SIR,—Will you allow me to ask some of your readers if they can help me to relieve severe pain occurring paroxysmally in the foot after hemiplegia, accompanied with tingling and numbness. Ointments of aconite and belladonna have exasperated it. The patient objects to hypodermic injections. Would it be wise to try the constant current? I have failed so often that I do not wish to resort to this without previously having the benefit of other experience than my own.—Yours faithfully,

March 30th, 1885. H. G. D.

TRANSMISSION AND TRANSMUTATION OF DISEASE.

To the Editor of THE LANCET.

SIR,—I shall be greatly obliged if any members of the profession will furnish me from their own experience any of the following:—1. A family tree showing the transmission of phthisis, gout, or rheumatism, through (if possible) three generations and one or more collateral branches of the family. 2. Any instances of the transmutation by heredity of nervous diseases—e.g., epilepsy, hysteria, alcoholism, &c., into insanity, or *vice versâ*. 3. Any good instances of the hereditary transmission of skin diseases. I am, Sir, yours faithfully,

Belfast, March 28th, 1885. JAMES A. LINDSAY, M.A., M.D.

COMMUNICATIONS not noticed in our present number will receive attention in our next.

The Publisher cannot hold himself responsible for the return of testimonials, &c., sent to the office in reply to advertisements; copies only should be forwarded.

NOTICE.—Advertisers are requested to observe that it is contrary to the Postal Regulations to receive at Post-offices letters addressed to initials only.

An original and novel feature of "THE LANCET General Advertiser" is a special Index to Advertisements on page 2, which not only affords ready means of finding any notice, but is in itself an *additional* advertisement.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Answers are now received at this Office, by special arrangement, to Advertisements appearing in THE LANCET.

Terms for Serial Insertions may be obtained of the Publisher, to whom all letters relating to Advertisements or Subscriptions should be addressed.

Advertisements are now received at all Messrs. W. H. Smith and Son's Railway Bookstalls throughout the United Kingdom, and all other Advertising Agents.

Tables of Contents, with the Index of Advertisements, for each Number can be had on application to the Publisher.

Lumleian Lectures

ON

SOME POINTS IN THE NATURAL HISTORY OF PRIMITIVE DRY PLEURISIES.

Delivered before the Royal College of Physicians,

BY SIR ANDREW CLARK, BART., M.D.,
FELLOW OF THE COLLEGE.

LECTURE III.

MR. PRESIDENT AND GENTLEMEN,—In the last lecture I arranged, for the sake of convenience, the pathological changes in the lung resulting from primitive dry pleurisies under four heads, and I intimated that for each of these there was to be found a corresponding clinical state or autonomy. I proceed now to consider these clinical states, to describe their chief characteristic signs, and to show in what manner they may be distinguished from other states resembling them, but having a different meaning and importance. The former, for descriptive purposes, I shall name the neoplastic pleural membrane state, the fibroid lung state, the bronchiectatic state, and the phthisical fibroid lung state.

And first of all, concerning the neogenetic pleural membrane state. The patient may have the aspect of health, and experience no subjective indications of the presence of disease. If any exist, they will be limited to uneasiness or pain in the affected side, an occasional dry cough, feverishness, and general malaise. On rare occasions the patient may be conscious of the existence of pleural friction. The physical signs are a slight decrease, with some irregularity, of the thoracic movements of the affected side, some diminution of the tactile vocal fremitus,[1] just notable but unequal dulness on percussion, a shifting, rubbing or grating friction, enfeebled breath sounds, and an altered vocal resonance. In some cases, instead of pleural friction there may be heard crepitation, crackling, or clicking; and we shall know from the superficial characters of these sounds, from their resistance to respiratory efforts, and from their association with gratings or rubbings that they are of pleural origin. Having thus before us a dry pleurisy, we have to determine if it is a primitive or secondary affection. If there are signs of disease in the corresponding or in the opposite lung, it is probable that the pleurisy is secondary; and if without such signs there is grave constitutional disorder, it is equally probable that the pleural inflammation has arisen out of some pre-existing malady; and this pre-existing malady may exercise its causal influence either through some local growth, such as tubercle, lying beyond the range of physical detection, or through some constitutional state, such as adenoma or syphilis. On the other hand, if there exist no signs of local disease, and no serious symptoms of constitutional disturbance, it is presumable that the case is one of primitive dry pleurisy. This affection may arise from mechanical injury, or from cold, and it may be a local expression of such non-malignant constitutional disorders as rheumatism and gout.

The future course of a case of primitive dry pleurisy depends upon causes seldom visible or calculable, and is therefore absolutely uncertain. The signs of the malady may subside in a few weeks, or they may continue for months, or they may come and go for two or three years, and then either entirely disappear or invade the lung. Sometimes after a variable duration the dry stage issues in serous effusion, which pursues its ordinary course, and ends eventually in a thickened pleura and a contracted lung. In one case seen with Dr. Sedgwick, and in another seen with Dr. Warrington, it appeared as if the structural elements of an old adventitious pleural membrane developed through metaplastic processes into malignant fibrous growths. This result, however, must be infinitely rare; and when the health of the patient is good, and he can be placed under the conditions most favourable to the organism, clinical experience will warrant the expectation of complete recovery. Nevertheless, it occasionally happens, in spite of apparent good health and skilful care, that the inflammatory process invades the lung and brings about therein a more or less extended fibroid induration. This fibroid lung state is of frequent occurrence, and from the mistakes liable to be made concerning it, and the course which it commonly follows, it is a subject of great importance as well as of great interest. It certainly demands, and will certainly repay, an extended and a critical study. We have, in the first place, to make sure that we are dealing with a fibroid lung state. What seems to be a simple fibroid induration[2] may be something quite different; or it may be that and something more. It may be essentially a tubercular consolidation with an unusually large amount of secondary fibroid growth; it may be a chronic caseous pneumonia; it may be a pleuritic effusion; it may be a malignant growth; and it might be several other things which for practical purposes need not now be considered. If the case has been followed from the beginning, no serious difficulties of diagnosis will be encountered; but if, as usually happens, the patient is not seen until the pulmonary consolidation is advanced, the greatest care will be required to avoid falling into serious error, and to succeed in framing a correct judgment. If there are no serious symptoms of constitutional distress; if there is no elevation of temperature and no hurry of circulation; if flesh, colour, and strength are little, if at all, affected; if in the consolidated lung there are no signs of disintegration, and in its fellow lung no indications of advancing and spreading disease,—the question of tuberculosis may be settled in the negative. And it may be so settled conclusively if after repeated examination of any sputum which may be ejected no tubercular bacilli are found therein.

With respect to caseous consolidations, they are of two sorts: one which is tubercular, and one which is not. From simple fibroid induration, the former may be distinguished by the presence of tubercular bacilli in the sputum. And as to the latter, if there is no history of a feverish illness; if there is no elevation of temperature, or quickness of the pulse, or cough, or expectoration; if there is material retraction of chest, with diminution of tactile vocal fremitus; if no râles are heard within or around the consolidated lung; and if the vocal resonance is either diminished or not increased,—then the hypothesis of any sort of caseous consolidation must be abandoned. Furthermore, if the patient has no cachectic appearance; if there are no irregular retractions of chest, no depression of shoulder and nipple, no pushing outwards of the lower part of the scapula; if, with extensive consolidation, there are no pains or signs of pressure, no extension of dulness beyond the normal limits of the lung, no displacement of heart, no distress of breathing with blood-stained expectoration, no rapidity of pulse without notable elevation of temperature,—it may be said with all but absolute certainty that a malignant growth is not the cause of the consolidation.

But in fibroid lung the condition which by far the most frequently gives rise to mistakes in diagnosis and errors in practice is pleural effusion. To mistake an ordinary and considerable serous effusion for a fibroid lung can happen only from want of competence or want of care. The fixed and rounded side; the tumid or even bulging intercostal spaces; the dulness, varying with position; the feeble breath sounds, except near the spine, where they are bronchial; the diminished resonances; the displaced organs,—if duly examined and considered forbid peremptorily every interpretation but one. Happily, however, the danger of mistake does not lie in this, but in an opposite direction; it lies in supposing that a solid fibroid lung is a fluid effusion. And here it must be confessed that, when the effusion is moderate in quantity and of long-standing, when the dulness does not vary with position and there is no displacement of organs, when the signs of local disease have descended from an acute pleurisy and there is no account of pulmonary disease, the difficulties of diagnosis are great and not always, without exploratory operations, overcome. For in both conditions, in the moderate fluid effusion and in the indurated lung, there are to be found diminished respiratory movements of the affected side, toneless dulness on percussion, decreased tactile vocal fremitus, feeble, hollow, or suppressed respiratory murmurs, and lowered as well as

[1] I do not forget that Dr. Walshe has spoken otherwise; and it is only after careful investigations, often repeated, that I venture to differ from one of the most accomplished auscultators of our time.

[2] Or, to use another terminology, an interstitial pneumonic consolidation, cirrhosis, sclerosis, or iron-grey induration.

altered vocal resonances. Nor, indeed, do exploratory operations always overcome these difficulties. Fluid may be present, and none be withdrawn by the needle. It may not penetrate the thick and hard pleura; it may carry the membrane before it, or it may become blocked by débris. But, notwithstanding this close similarity of physical signs between affections so widely different, grounds of distinction between them, if narrowly sought for, may be in most cases discovered. In the first place, the continuous history of an illness beginning with an unmistakable pleurisy, and passing straight into a basic dulness of doubtful nature, points strongly, but not necessarily, to fluid effusion; not necessarily because a fibroid induration, although it sometimes originates and advances unattended by inflammatory or other local or general symptoms, occasionally arises in, or immediately follows, a pleural inflammation; or is begotten by substitution out of an unabsorbed pneumonic exudation. In the second place, if we are dealing with a fluid, and especially if that fluid be purulent, there will probably be present some degree of fever, and almost certainly some acceleration of pulse; in a fibroid consolidation there need be neither the one nor the other. In the third place, if fluid be present and confined to a portion of the pleural sac, the side, although generally flattened or retracted, will be swollen over the part where the fluid is collected; the intercostal spaces will be effaced or more or less bulged; the diminution of the tactile vocal fremitus will be uniform; the dulness on percussion will be more diminished in volume, raised in pitch, shortened in duration, and lessened in resistance than when dealing with a fibroid induration; the breath sounds will be feeble or suppressed; there will be no râles; and the vocal resonance lowered and altered may be ægophonic. In the fourth place, we may conclude that we are dealing with a solid lung if, with the signs already described, we find that the affected side is everywhere, and especially irregularly, contracted, that the intercostal spaces are deepened, that the dulness is accompanied by great hardening and resistance, that the tactile vocal fremitus, much diminished, is unequal throughout the dull region; that there is rubbing or creaking; that there are râles of any description, superficial or deep; that the vocal resonance, increased or diminished, and varying at different parts, has a metallic quality; and that there is some, however slight, displacement of organs to the affected side. Having thus cleared away the various sources of error in diagnosis, and having made sure that we are dealing with a fibroid lung, I proceed to set forth its clinical characters and course.

I shall, in the first place, consider the local physical signs, and in the second, the constitutional state. Among many descriptions drawn from life of the physical signs of fibroid lung I possess in particular two, one of which was written in conjunction with Dr. Pollock in 1868, and one with Dr. Douglas Powell in 1885. As concrete examples will strengthen the general description, and as the authority of those justly distinguished physicians will stamp with accuracy the relation of the physical signs in the cases examined, I herewith reproduce them

Dr. Pollock's case, examined with Dr. Andrew Clark, October 21st, 1868.—A farm labourer, well nourished, rosy, and of healthy aspect, fifty-seven years of age, and of regular and temperate habits, complains of occasional cough, slight morning expectoration, and breathlessness on exertion. His father died at sixty from renal disease; his mother, aged eighty-six, is alive and well; two sisters are living and in good health; two brothers and sisters died from causes unknown. In 1860 the patient had trouble, presumed to be pleuritic, in his left side, and after some weeks got well. In February, 1868, eight months before this examination, the patient caught cold, shivered, felt sharp pain in the left side, became feverish, had a little cough, and was confined to bed; had night sweats some time in March; in April or May was well. The digestive organs are in fair condition; the urine is abundant, sedimentary, of low density, and contains a considerable amount of albumen. The left side of the chest is flattened from the clavicle to near the nipple, in the lower part of the axillary region, and about the posterior base. The impulse of the heart is felt immediately under the left nipple, and its action, unaccompanied by murmurs, is normal; the pulse is about 80.

Examination of left side.—Above the clavicle the percussion note is normal; from second rib to anterior base, except near the sternum, there is absolute dulness, which nowhere passes the median line. In the lower half of the axillary region, and posteriorly from the spine of the scapula to the base of the lung, there is marked and increasing dulness; in front, from summit to nipple, in the upper half of the axillary region, and posteriorly in the supra-spinous fossa, and for a little way below the spine of the scapula, the tactile vocal fremitus is increased; elsewhere it is in different degrees at different parts demolished. Upon auscultation the following signs are elicited. In the supra-clavicular region there is normal vesicular breathing, but an occasional wheeze is heard at the close of inspiration, and the expiration is prolonged. From the clavicle to the second rib the inspiration is rustling; the expiration prolonged and blowing. Between the second rib and the nipple the respiration is bronchial and the vocal resonance is altered and increased. From the nipple to the anterior base the respiratory sounds and the vocal resonance are suppressed; only a faint creaking, crackling, or rumbling is heard. In the upper part of the axilla there are heard pleural creaking, bronchial breathing, and a modified bronchophony; in the lower part all sounds are suppressed. In the supra-spinous fossa the respiratory sounds are loud, harsh, and accompanied by crepitation, which, on coughing, becomes a crackle. There is no increase of vocal resonance. From the spine of the scapula, where they are weak and hollow, the respiratory sounds become fainter towards the base, and are there wholly suppressed. In no part of the right lung can any sign of disease be discovered. In 1878 the patient was reported to be in the same condition; but since then he has not been seen.

Dr. Douglas Powell's case, examined with Sir Andrew Clark on Jan. 7th, 1885.—The patient is a dark, stout, florid, healthy-looking man of fifty-four, and has no complaint except that he is breathless on exertion, and that he gets a little cough and expectoration in cold and damp weather. He has been slowly gaining flesh and strength for the last six years. In 1863 or 1864 patient had some serious trouble in his left side, and was ill for seven weeks. In 1866 he had a fresh illness with pains in his left side, and "a feeling as if there were two holes in his lung when he took deep breaths." Was first seen in November, 1867, by Dr. Andrew Clark, who reported the case to be one of chronic dry pleurisy, with secondary fibroid induration of the lung. About this time he was for six months an inmate of the Brompton Hospital, where he was repeatedly examined by Dr. Douglas Powell. The left side of the thorax is flattened and irregularly retracted, rises imperfectly and unequally on inspiration, and measures on the level of the nipple sixteen inches and a half, being one inch and a half less than the measurement of the opposite side at the same place. The left shoulder is depressed and angular; the left nipple corresponds to the fifth rib. The lower part of the axillary region is protuberant, and the upper retracted. The inferior angle of the scapula juts outwards from the ribs. The impulse of the heart is felt under the left nipple, and its action is slow and normal; the pulse is full, soft, and compressible. The percussion note, slightly tubular in the supra-clavicular space, and normal just below the clavicle, becomes increasingly dull to the base, where the dulness is absolute. In the axillary region there is dulness throughout, slight above, moderate in the middle, absolute at the base. Posteriorly dulness begins below the spine of the scapula, and increases to the base. The tactile vocal fremitus, normal at the summit and increased at the middle of the axillary region, is everywhere else either greatly diminished or entirely suppressed. About the summit of the lung the respiratory sounds are harsh, but of the vesicular type, and the expiration is prolonged; there are, however, no râles. About the middle of the axilla there are heard superficial creaking or rubbing, with occasional coarse crepitation and dry rhonchi, elsewhere the respiratory sounds are feeble, hollow, distant. The vocal resonance, loud in the supra-clavicular region and just below the clavicle, is bronchophonic in the middle and upper part of the axilla; at the base it is suppressed, and in other parts diminished. The right side of the thorax, full and rounded, rises fully on inspiration, and yields to examination no evidence of disease. The digestive organs are in excellent order. The urine, with less than an average discharge, has a specific gravity of 1014, is acid, clear, and contains no trace of albumen or of sugar.[3]

From these two cases, average specimens of their class,

[3] Since the delivery of this lecture Dr. Douglas Powell has reminded me that on more than one occasion the urine of this patient has been slightly albuminous.

a tolerably complete account may be obtained of the physical signs characteristic of the fibroid lung, and from the records of Dr. Douglas Powell's case one will now see how one may reasonably demur to the propriety of designating by the term chronic interstitial pneumonia a state of lung which has been quiescent for years, develops no general symptoms, and is compatible with more than average health. In these circumstances the terms sclerosis or fibroid ought, I think, to be preferred, inasmuch as they indicate with sufficient accuracy the physical characters of the pathological change, involve no hypothesis, and may, whilst hypotheses change, remain unchanged.

The local physical signs of pulmonary fibroid induration of moderate extent may be now formally enumerated, and they are as follows. The disease is commonly unilateral; the affected side is irregularly flattened or retracted; the shoulder is depressed, the lower angle of the scapula is tilted outwards, the spine is sometimes a little twisted, and the respiratory movements, especially the movement of expansion, are defective and irregular. The tactile vocal fremitus is diminished; there is more or less dulness on percussion; pleural rustlings, crepitations, cracklings, creakings or frictions are always at some time audible; the respiratory sounds are usually feeble, hollow, distant; from time to time there are crepitations which are often of a metallic quality, with moist or dry mucous rhonchi.

Such are the physical signs in favourable cases of fibroid lung, where the elasticity of the parenchyma is but moderately diminished and its nutritive conditions are not seriously disturbed. When, however, the base of the lung, surrounded and invaded by indurated lymph, has lost a great part of its elasticity, and the bronchial mucosa, stimulated by undue supplies of altered blood, secretes a more or less viscid mucus which cannot be expelled, bubbling rhonchi of metallic quality are heard in the affected region, and there arise recurring paroxysms of cough, which succeed, only by the help of retching, in emptying the bronchial tubes. Although this condition invades the comfort of the patient, it does not, unless greatly aggravated, seriously injure the health or obviously limit the duration of life. But when the lung becomes more and more rigid, and the bronchial tubes fill more easily with secretion, which is with increasing difficulty expectorated, the patient begins to suffer, and through secondary congestions, consolidations, emphysemas, and perhaps bronchial dilatations, both health and life are placed in peril. The constitutional symptoms accompanying fibroid lung vary according to the state of the induration. When this is not advanced enough to destroy the pulmonary elasticity, when the bronchial secretion is not in excess of what can be easily expectorated, and when the patient is kept under favourable physiological conditions, the general health is little if at all affected. It is true that he becomes breathless on exertion, that his general power of resistance to disturbing causes is lowered, and that from small provocation he falls into bronchial gastric or vesical catarrhs. Nevertheless, with just guidance and loyal obedience to it the patient may continue beyond the average duration of life to live and work. On the other hand, when the induration has destroyed the elasticity of the pulmonary parenchyma and the bronchi are filled for hours with sputa, which cannot be discharged, and perhaps undergo septic change, the constitution suffers; sometimes there is gastric, hepatic, and enteric catarrh; sometimes the urine falls in density and becomes more decidedly albuminous; sometimes the face and neck become swollen and the veins of the affected side enlarged; sometimes the feet become œdematous; and always, even with increased frequency of pulse, the temperature falls below the normal standard. But even in these conditions, with his comfort invaded and his capacity for work narrowed, the patient may return to the favourable stage of his malady, or without doing so may reach the longest term of life. The albuminous urine existing in the great majority of cases of fibroid lung seems to be of small importance in its earlier stages. But in its later and more unfavourable stages, when the bronchi are almost always loaded, and the lung becomes increasingly hard and congested, and the circulation is hurried and feeble, and the skin cold and harsh and dry, the condition of the kidneys becomes greatly aggravated, and at last puts an end to life. Indeed, in the greater number of cases, it is the renal and not the pulmonary affection which puts an end to life.

Proceeding now to the bronchiectatic lung state, I have to observe that its clinical characters have been elsewhere so admirably and exhaustively described that I do not feel justified in occupying the time of the College by giving another description, which I could not execute so well, and to which I could add so little. Nevertheless, I desire to notice some points in the clinical history of bronchiectasis, either because they have not been dwelt upon before, or because they have been inadequately or erroneously described. In the first place, the general condition of the bronchiectatic patient differs materially from the subject of tubercular phthisis on the one hand, and of fibroid lung on the other. Pale or cyanosed, for the most part thin and stooping, distressed by paroxysms of cough and drained by discharges of purulent and sometimes fetid expectoration, the subject of bronchiectasis displays a combination of mental and bodily engergy not to be met with in any other disease. In the second place, whilst in fibroid lung the disease is for the most part unilateral and in tuberculosis bilateral, in bronchiectasis both forms occur in nearly equal numbers. In the third place, whilst bronchiectasis resembles fibroid (for which it could not well be mistaken) in temperature, circulation, forms of cough, kinds of expectoration, conditions of breathing, absence of malaise, and slowness of general progress, it differs in almost all these points from tubercular phthisis, with which it is frequently confused and has nevertheless little in common. In the fourth place, whilst the excavations of fibroid occur at any part of the lung and the excavations of tubercular disease at its summit, and whilst the excavations of both, when they are multiple, appear in groups without definite form or order, the dilatations of bronchial tubes, found more frequently at first in the middle and lower than in the upper lobes, are arranged in order along the bronchial ramifications. In the fifth place, whilst the excavations of fibroid and tubercular disease arise in the midst of consolidations, the bronchial dilatations have no necessary relations to them, and, although commonly surrounded by fibroid induration, may be often found in the midst of apparently unaltered lung. In the sixth place, although bronchial dilatations may be unsurrounded by peribronchial thickenings, or by pulmonary induration, chronic pleuritic neoplastic membranes are never absent. In the seventh place, when several cylindrically dilated bronchi lie near to each other, the physical signs are sometimes such as to suggest the existence of a large cavity with rigid walls; but a careful and often repeated study of those signs will prove that they vary with the amount and time of the expectoration, and that sometimes the signs of a cavity are often wanting, and that at other times they are present only in isolated parts. In the eighth place, in opposition to Traube and others, I contend that the sputum in bronchiectasis, similar in characters to that of advanced and regressive fibroid, frequently contains fragments of elastic tissue in two forms: first, in the form of bands, consisting of fibres running in straight lines parallel to each other; and, secondly, in the form of elastic areolæ and thickened intersecting trabeculæ. The former are exfoliated from the bronchial mucosa; the latter come from the pulmonary alveoli disintegrated by ulceration proceeding outwards from the bronchial dilatations. In the ninth place, the sputum in uncomplicated cases of bronchiectasis, accompanied or unaccompanied by fibroid indurations and excavations, does not, as far as my present experience extends, contain tubercular bacilli. In the tenth place, the only certain means of distinguishing a tubercular from a bronchiectatic cavity, or of knowing when a tubercular has supervened upon a fibroid or bronchiectatic process, is the presence in the sputum of tubercular bacilli.

Leaving now the bronchietatic lung state, I proceed to consider the chief points in the clinical history of the phthisical fibroid lung. As before, I will discuss, first, the local and physical signs, and thereafter, the constitutional or general symptoms. The physical signs of the phthisical fibroid lung are the same as those of the simple fibroid lung, with certain alterations and additions. The disease is for the most part unilateral; and when we inspect the chest, we observe the same flattening or retraction of the affected side, the same depression of the shoulder and nipple, the same leaning of the body to the affected side, the same approximation of the ribs and hollowing of the intercostal spaces, the same displacement of the cardiac impulse and throbbing at the root of the pulmonary artery,[1] the same projection of the lower angle of the scapula and twisting

[1] This throbbing at the root of the pulmonary artery is sometimes mistaken for the systolic impulse of the left auricle.

of the spine, the same restricted movements of inspiration, and the same rounded fulness and compensatory expansion of the unaffected side. By palpation and percussion we elicit results resembling those elicited by examination of the fibroid lung: diminution in varying degrees of tactile vocal fremitus, sometimes friction fremitus, and dulness on percussion, seldom over the upper, usually over the lower lobes, and most frequently at the posterior base. Upon auscultation we hear over the summit a harsh and jerking respiratory murmur, prolonged expiration, perhaps some medium crepitation or dry rhonchus, and increased vocal resonance. Over the dull regions there will be heard feeble breath sounds, coarse crepitations, and bubbling rhonchi, usually metallic in character; at some parts the vocal resonance will be diminished, and at others increased. At one or two spots in the base or middle of the lung, very rarely at its summit, there will be found a tubular percussion note, increased fremitus, cavernous breathing, bubbling or smaller gurgling râles, and piercing bronchophonic voice resonance. Throughout the lung opposite the affected one the respiratory murmur, penetrating everywhere, will be found loud, harsh, and accompanied by a few rhonchi or by scattered moist crepitations, which come and go. The patient has paroxysms of cough, making the face swollen and livid, and ending sometimes in dry retching, sometimes in the expulsion of several ounces of expectoration. This expectoration, sometimes gelatinous or muco-purulent, sometimes in discrete opaque masses like softened cheese, sometimes watery, sanguinolent, or fetid, contains in a mucoid or granular matrix pus-globules, granule-cells, blood-discs, epithelial cells, bands and areolæ of elastic tissue, and the débris of decaying structures swarming with micrococci. The breathing, quiet when at rest, becomes, on moving about or on coughing, shallow, laboured, and quick. The heart, drawn to the affected side, may be acting vigorously and with moderate frequency; there will be probably a systolic bruit in the pulmonary area; the pulse will be of moderate volume, and the superficial cervical veins will be distended. If the disease is much advanced, the face and neck will be swollen, and the integument over the side of the affected lung may become œdematous; the pulse will increase in frequency and diminish in volume, and the extremities will become cold and damp. The digestive organs are more or less deranged through hepatic and gastro-enteric catarrh; the liver is enlarged, there are often hæmorrhoids, and the bowels are confined. Almost invariably the urine falls in density and contains albumen; and this condition of the renal secretion is one of the features which, with others to be mentioned, make so striking the difference between fibroid and tubercular phthisis. The patient is often fairly nourished, sometimes corpulent, and, unless there is much bronchiectatic disease, seldom thin. In a few cases he becomes cachectic-looking and anasarcous. The nervous system, except towards the close of the disease, is seldom seriously disturbed. Only one symptom occurs sufficiently often to be regarded as characteristic; this is pain about the base of the affected lung. Present in many cases, sometimes slight, sometimes severe, occasionally occurring in paroxysms which play around the attachments of the diaphragm and pass downwards into the abdominal walls, this pain, regarded as a neuralgia, is considered by the patient to be the essential part of his malady, and causes him, in fact, his chief if not sole complaint.

With such serious signs of disease, and with such an assemblage of symptoms depending thereon, it might well be thought that the patient was in constant suffering and in imminent peril; and yet, strange to say, it is sometimes quite otherwise. The symptoms which seem the most distressing cause him either little suffering or suffering which is immediately forgotten; and soon after a paroxysm of coughing, in which death from mechanical violence or suffocation or exhaustion seems inevitable, the patient may be found full of business, sparkling with humour, and confident of life. Here is another of those features of fibroid which serve to distinguish it from tubercular phthisis: the frequent concurrence of extensive disease with an abounding vivacity and abiding life. For although often it seems as if the patient must succumb, yet as often he rallies, and, renewing his conflicts and repeating his victories, he continues in the fervour of self-reliant hope to live and fight and to enjoy work.

Here, then, is the eventual outcome of a primitive dry pleurisy, which, after lasting for an uncertain time, has invaded the lung, altered or destroyed some of its structural constituents, consolidated portions of its parenchyma, and brought about ulcerous excavations therein. Here are well-defined pathological, corresponding with well-defined clinical, conditions moving forward together with constantly re-adjusted relations towards a definite issue. Here are an assemblange and progression of symptoms associated with or dependent upon an ulcerative destruction of more or less circumscribed non-malignant deposits in the lung. What is the name whereby we make known to each other the existence of this complex state? We call it pulmonary phthisis, and the term has so penetrated every department of thought and work in medicine that it can no more be rooted out. This final outcome of pulmonary fibroid invasion is therefore a pulmonary phthisis. And if nothing more could be said, here at last would be an end of the whole matter. But, for my own part, I believe that on this subject there is more to be said; and to those who have sufficient experience and settled convictions I regard it as a duty to say it. Such saying may clash with established opinion, assume the aspect of a retrograde movement, and be even inaccurate. Nevertheless, it ought to be welcomed; for genuine thought born of genuine work must always in science have its place and use. What, then, if under the term pulmonary phthisis there are included several states, which, although corresponding to the generic definition, are different in their characters, course, duration, and issues? If they exist, ought not such states to be named, and so named that the ideas which they express, and the distinctions which they embody, shall be preserved for future study and use? It cannot be a worthless knowledge which will enable one in a given case to predict with accuracy its future course, and say whether the subject of it is to live for five or for fifty years. And, furthermore, if such states have vindicated their right to be named, upon what principles shall the names be bestowed? Surely, if we wish to avoid confusion of thought and speech, surely if we wish to repress that needless ever-changing nomenclature, that substitution of words for ideas, that reproduction of old thoughts disguised under freshly furbished raiment, which in knowledge so often begets movement without progress, we shall make sure that the name given shall be based on some physical characteristic of the thing named; so that whilst theories of its nature may change, the name bestowed upon it, and by which it becomes everywhere and by everyone understood, shall remain unchanged.

Now, my contention is that our answers to all these questions should be in the affirmative. I contend that there is a general assemblage of pathological conditions upon which we may bestow the generic term phthisis; that included in this term are subsidiary groups of states, which, differing each from the other in some essential points of their pathological and clinical history, demand separate recognition; and that, in naming them, we should have exclusive regard not to the ephemeral theories of their nature, but to the abiding facts of their physical constitution. Guided by these considerations, I regard the ultimate condition of the lung invaded, altered, consolidated, and excavated by fibroid material as a phthisis; and seeing that the most obvious and unvarying fact in its physical constitution is the presence and action of this very fibroid substance, I am bold enough to call it fibroid phthisis. This boldness will doubtless call down upon me a storm of reprobation and denial; be it so. Confident that there is at least some just foundation for the position which I have taken, I must be content to endure and wait. In reply to this contention it will be said that the subject is no longer open to discussion; that experimental, pathological, and clinical inquiries concur to prove that there is but one phthisis, the sole originator of which is the tubercular bacillus; that there is neither room nor need for subsidiary classifications; and that their advocacy can be accounted for only by the ignorance or incompetence of the advocates. But these arguments, couched in such courtesies of modern controversy, are not so conclusive as they sound and seem. Many answers may be made to them, but on the present occasion I shall confine myself to two, which, as I venture to think, are neither light nor irrelevant.

In the first place, assuming the absolute unity of phthisis under the exclusive causation of the tubercular bacillus, this unity does not do away with the fact that there are included in it subsidiary groups which, for reasons already given and not refuted by the bacillary presence, require separate and permanent recognition. At present the bacillary hypothesis, although supreme in the domain of pathology, continues to be of but small account or even barren in the field of practical medicine. We

cannot prevent the entrance of the bacillus into the organism; we cannot follow it into the secret places where it dwells and works; we cannot reach it by drugs, nor put an end to its multiplication by taking refuge among the mountain tops. But although we cannot eradicate the bacillus nor arrest its action upon the organism, we may perhaps succeed in helping the tissues to resist more or less successfully the attacks which it makes upon them and the destruction which follows in their wake. And, although in addressing ourselves to the furtherance of this object, we must have regard in the first place to the general well-being of the organism, we must not be unmindful of the different structural effects which arise from the unitary action of the bacillus. We must remember that sometimes these structural effects appear under the form of tubercles, sometimes under the form of caseous masses, sometimes under the form of fibroid consolidations, and sometimes as combinations of these forms, in which, however, one form is always predominant. Now, it can scarcely be denied that there is some difference of meaning in these differences of structural effects; that they pursue different courses; and that they react in different ways to the influences of climate, food, alcohol, and drugs. And if this be so, I can discover no valid reason why those different groups should not be recognised by distinctive names, nor can I understand how we are to preserve a complete loyalty to the uses of knowledge if we continue to refuse them recognition. It can be no invasion of the rights and privileges of the bacillary suzerainty to grant subordinate autonomies to the several groups of states which, arising under its influence and continuing through its presence, pursue independent courses and create widely different histories. Why under the generic name bacillary phthisis should we not recognise the subordinate independence of tubercular bacillary phthisis, caseous bacillary phthisis, and fibroid bacillary phthisis? Surely every just differentiation is a substantial gain, and every confounding of things fructively distinct a material loss. In the second place, I hold that the assertion that all ulcerations of non-malignant deposits in the lungs are bacillary remains unproved, and is opposed to the results of inquiries made by several competent observers. I contend, on the contrary, that there exist cases of ulcerative bronchiectasis and of fibroid lung with excavations in which, after repeated search by processes successful in veritable tuberculosis, no tubercular bacilli could be found. It is to such cases that I give the name of non-bacillary fibroid phthisis.

It may now be justly asked, Would anything be gained by establishing this distinction? I think much in many ways. It is, however, of the clinical gain alone that I shall at present speak. By adopting and carefully studying the proposed distinction, we should learn that the history of non-bacillary fibroid phthisis is quite different from that of bacillary tubercular phthisis, and that the treatment which would prove useful in the one might prove both useless and injurious in the other; for example, alcohol which is usually helpful in caseous, is usually hurtful in fibroid phthisis. If anyone will critically compare the broad facts making up the history of tubercular with those making up that of fibroid phthisis, I think he will become disposed to admit that the distinction now contended for is both real and considerable.

Let me bring to your remembrance a very few of the contrasting facts which are found in the two forms of phthisis now under consideration.[5] Tubercular phthisis is primarily of constitutional origin, and appears for the most part in the young; it is bilateral; its course is accompanied by elevation of temperature and rapidity of circulation, by progressive loss of flesh, strength, and colour, sometimes by laryngeal ulceration, and sometimes by sensations of painful exhaustion and malaise; it is usually rapid in its progress; the majority die within three years; and the few who, in consequence of fibroid complications, live for several years, enlarge the average duration of the disease to four or five. On the other hand, fibroid phthisis is usually of local origin, and appears for the most part in the middle-aged; it is in the main unilateral; it is unaccompanied by elevation of temperature or hurry of circulation; flesh, colour, and strength may remain but slightly affected for years; it is not incompatible with great bodily and mental energy; the urine almost always contains a little albumen; the progress of the malady is slow; œdema is never absent throughout; and death, which seldom occurs within five years, often lasts for thirty.

Here I must bring these lectures to an end. Acutely sensible of their shortcomings, I regret that they have not been worthier of the occasion, of the place, and of you. Nevertheless, I take courage of heart in the thought that those who have worked the most, and thought the deepest, and can judge the best will not be ready to forget, or to despise when remembered, the small but sometimes perfect uses of imperfect work.

[5] That is, there exist in the organism certain peculiarities of soil which enable the bacilli to grow and multiply.

ON THE

THERAPEUTIC VALUE OF ARSENIC IN ANÆMIA AND ATROPHIC CONDITIONS.

BY SAMUEL WILKS, M.D., LL.D., F.R.S.

ALTHOUGH the value of arsenic in many diseases is well known, yet I believe the extent of its efficiency has by no means spread through the profession at large, judging from the frequent scepticism one meets with when its use is suggested. I should therefore wish, as briefly as possible, to state my experience of the great value of this most remarkable remedy during many years of practice. It has been best known as a medicine in skin diseases, but this only of late years, for Addison, who followed directly in the school of Willan and Bateman, rarely ordered it. Next to its use in cutaneous affections has been its administration in neuralgic affections and ague; after that in special cases of various kinds. More recently the great value of arsenic has been recognised in anæmia; but it is not widely known, I believe, as being equally efficacious in various forms of cachexia, of which I am about to speak.

When a remedy acts—to adopt the expression of the older schools—as an alterative, by modifying nutrition in some unknown way, a question arises which is quite open to consideration: whether those diseases which succumb to its action may not depend upon the same cause; whether, indeed, they are not bound together by some common origin. Be this as it may, there can be no doubt that many of the cutaneous affections cured by arsenic have a gouty origin, and therefore it is not surprising that the same remedy has a great power in preventing attacks of gout. This I have known for many years, and in some cases have by its use undoubtedly kept the attacks in abeyance. Then, this gouty class of persons are often neuralgic, and it may be in them especially that arsenic is the best nervine remedy. I have certainly found it amongst the most efficacious medicines, and in some cases the only remedy. Thus, before the introduction of nitrite of amyl and glonoin for angina pectoris I relied mainly on arsenic, and in some cases kept off attacks for weeks when they had previously occurred almost daily; but this is by no means a novel treatment, for a reference to THE LANCET of May 26th, 1832, will show a letter setting forth the virtues of arsenic in this complaint. In some forms of nervous affection I have found it quite unique in its action. For example, a lady for many years has been the subject of ciliary neuralgia—that is, she has attacks of violent pain in the eyeball accompanied by intense congestion and lacrymation. No ophthalmic surgeon to whom she has applied has afforded her the slightest relief either by medicines or local applications. The only respite she has from her sufferings is during the time she is taking arsenic. How I became acquainted with the use of this remedy in asthma from one of my out-patients I described many years ago.

But the most remarkable effects of this remedy are seen in anæmia and various forms of cachexia and atrophy. My attention was first markedly drawn to it in this connexion owing to the controversy which took place between my late colleague, Dr. Alfred Taylor, and others in reference to the statement published in Johnston's "Chemistry of Common Life" in the year 1855 about the arsenic-eaters in Styria. Young girls were said to add to their charms by using it, acquiring blooming complexions, full rounded forms, and a healthy appearance. Soon afterwards I began to use arsenic in chlorosis with much benefit, but it was not until about ten years afterwards that I had some striking examples of its good effects. If I remember right Dr. Sutton

of the London Hospital was then using it in the same class of diseases. The case I especially recollect was a lady about forty years of age, who was pronounced by myself and other physicians to be the subject of idiopathic anæmia, the form of disease subsequently discovered by a German, and styled "pernicious anæmia." Her bloodless and feeble condition compelled her to keep her bed, and it was never believed that she would rise from it again. I suggested arsenic as a possible useful remedy, and she began soon to improve, and in a few weeks was able to come to my house. I saw her some years afterwards, in 1874, when she was quite well. The case is more especially impressed upon my memory on account of the remarks of the husband. When I told him of the remedy which had cured his wife he expressed no surprise, saying it was just the medicine he should have thought of, for if he had a horse which was not "thrifty" he gave it arsenic, rendering it again plump and its skin glossy. Subsequent to this case I have had several of a similar kind, my last one being only a few weeks ago. It was that of a gentleman living at Holloway, and whom I saw with Dr. Blackstone. He had gradually grown anæmic and breathless, so as to be unable to leave his house, and he walked with much difficulty. I called it one of idiopathic anæmia, and feared that he would never recover. He took five drops of liquor arsenicalis, and in a month he was comparatively well. In most of the cases where arsenic has succeeded, iron had previously failed; and it is a question, therefore, whether the latter be of any use in the so-called pernicious anæmia. This, however, does not seem invariably the case unless the diagnosis is at fault. For example, a woman came into the hospital in so bloodless a state that she could not leave her bed, and it was said that iron had been given in vain. An examination of the blood displayed, as was thought, characteristically altered blood-globules, and arsenic was prescribed. After a long course of this medicine she was no better, when iron was ordered for her. She then immediately improved, and left the hospital well.

I remember two cases of anæmia with some discolouration of the skin, suggesting the existence of Addison's disease, and which were cured by arsenic. One was a lady whom I saw as long ago as 1869, who had gradually been getting thin, sallow, and bloodless. She was first thought to have liver disease, and then Addison's disease; but of these there was no evidence, and I recommended arsenic. She speedily recovered. The other case was that of a lad who was sent to me from Suffolk by Dr. Manthorp as he was supposed to be the subject of Addison's disease. He was anæmic, sallow, very feeble, and breathless on exertion. Arsenic was given him, and he completely recovered.

It is another class of case, however, which especially prompted me to take up my pen and extol the virtues of arsenic, for although its efficacy is known in anæmia, I do not find that a knowledge of its merits has extended to wasting and general cachexia. It was in the year 1868 that I went to see a lady who was confined to her bed and in an extreme state of emaciation. I found on physical examination nothing tangible except an enlarged spleen. She had been staying at a friend's house in a doubtfully malarious district, and therefore might have been infected by ague poison. Arsenic was given, and she made a rapid and complete recovery. It is well known that in cases of inveterate malarious poisoning arsenic is often the best remedy, but the possible existence of such a cause will not account for the marvellous effects of arsenic in other cases; and I have notes of two patients who lived at Margate, where a miasmatic influence could not be suspected. The first case was that of a lady sent to me by Dr. Thornton. She was much impoverished, and at the same time had loss of appetite and other gastric symptoms, so that I suspected early malignant disease. I could not, however, prove this, and suggested a trial of arsenic. The result is seen in a letter which I received from Dr. Thornton, dated December 1875, in which he says, "I fancy you will be pleased to know that Mrs. B——, for whom you prescribed arsenic, and of whom you took not the most sanguine view, thinking probably that some hidden malignant disease might develop itself, strange to say, is now convalescent—that is, she has recovered her natural complexion, lost all pains and feeling of debility, and, indeed, is as well as she has been for the last few years. I never saw a more unpromising case, and I do not remember ever to have seen anyone improve so steadily as she did under the influence of arsenic (?); at all events, she was very ill, and now she is comparatively well."

The second case from Margate was that of a young man resident in that town, and brought to me by Mr. Dunstan of Tollington-park. He was twenty-one years of age, and had been gradually wasting away for many months until he had become, as his friends said, a perfect skeleton. He certainly was emaciated to a most extreme degree. On examination I failed, like other medical men, to discover any disease, but saying that if the patient had been an infant he would have been called the subject of marasmus. I suggested arsenic as the only likely remedy to do him good if he had no organic disease, and four drops of the solution were prescribed three times a day. He immediately began to recover; in two weeks he had gained five pounds, and in a few more weeks he was perfectly well.

Another case where the remedy was of great service was that of the Rev. Mr. S——. He had been acting as curate both in London and Brighton, but, his health gradually failing, he was obliged to give up his duties. No medical advice was of any value to him, and he was recommended to take a voyage to Australia. He, however, grew worse and worse, and on his arrival at Melbourne he was sent into the hospital. After a while he was again placed on board ship, under the care of a medical man, and sent home to Hampstead. He was carried into the house, being far too weak to walk, and when I saw him I found him as wasted as any living man could be. He was lying on a couch too feeble to rise, and very little more than a skeleton. His weight on leaving the ship was 5 st. 7 lb. With the exception of a cardiac bruit I found no disease, and as he had had every kind of medicine, and every variety of essences of meats and other foods, there seemed little for me to do; but I prescribed arsenic. He slowly began to improve, and in a few weeks he was able to leave his home and visit me. He walked feebly, but his limbs had increased in size, and he weighed 7 st. 10 lb. He then left for the country and the Continent.

I have now mentioned a sufficient number of cases to show the value of an old remedy, and certainly one of the most remarkable in the Pharmacopœia. I would not have it supposed that it cures all cases of anæmia and atrophy, or that it has never failed in my hands; for if I collected all the cases in which I have given it and noted the result, it is probable that the failures might equal the successes. But an explanation will show that a statistical method of arriving at the truth is of no value, seeing that the cases where the remedy was administered were not of a like kind, and that the unsuccessful cases, although resembling in outward appearance those of simple anæmia and atrophy, were in the majority of instances examples of early malignant and other organic disease. The only cases which can be rightly compared are those of a like kind, but the question of its comparative value under the circumstances named cannot affect in any way the undoubted fact of its curing numerous cases of apparently fatal disease. No question can arise as to the efficacy of a medicine when it is prescribed for a person who is weekly and monthly declining in health, and who as rapidly, or more rapidly, regains his health and strength under its use. When this has been observed in a large number of instances, the proof of its value is complete. I have never given very large doses, generally four or five drops of the liquor arsenicalis three times a day, or a little more of the soda preparation. I have never observed any injurious effects from its long use, although, as is known, it becomes absorbed into the system, the urine showing its presence many weeks after its administration has ceased. I will not pretend to say how the remedy acts. Why, when wasting is going on and the blood-corpuscles becoming disintegrated, arsenic should stop the process, and the globules begin to grow, or why it should allow the carbon to be stored up as fat, I do not know. I lay the clinical facts before my readers, and hope that those to whom they are not altogether new will excuse my doing so in the wish to make their knowledge and mine more extended and useful.

Grosvenor-street, W.

BEQUESTS.—The late Miss Duthies of Ruthvieston has, we understand, bequeathed the following among other legacies to public institutions in Aberdeen:—The Royal Infirmary, £2000; the Aberdeen University, for two medical scholarships, £2000; the Hospital for Incurables, £500; the Lying-in Institution, £500; the General Dispensary, £500; the Hospital for Sick Children, £500.

ON A CASE OF OBTURATOR HERNIA.

BY RICKMAN JOHN GODLEE, M.S.,
ASSISTANT SURGEON TO UNIVERSITY COLLEGE HOSPITAL.

CASES of obturator hernia are so uncommon and present such difficulties of diagnosis and treatment, that it may be well to place the following one on record, although strangulation had been in existence for so long that there was little hope of any treatment giving relief, and that adopted did not save the patient.

E. F——, a woman aged forty-five, was admitted under my care into University College Hospital on May 29th, 1884, at 8 P.M. with symptoms of intestinal obstruction. We were unable to obtain any good previous history of the case, and the notes do not mention the length of time from which she had been suffering from symptoms of complete obstruction; but they had been in existence for several days, I think about five, and she had for some time been bringing up fæcal vomit. She was on admission in a state of great collapse, with small pulse, cold extremities, and a marked blue colour of the skin. She complained principally of pain about the region of the umbilicus, or rather above it, and it was only on carefully examining all the hernia regions that it was found that there was distinct tendernees and slight fulness in the left Scarpa's triangle. On questioning her about this point, she allowed that for a long time past she had been subject to pain in this part, which extended down the front of the thigh and which was subject to variations, and was relieved by lying down; but it was evident that occasionally it had caused her considerable inconvenience. The diagnosis apparently lay between some twist or internal strangulation and an obturator hernia (though the possibility of the obstruction depending upon the presence of a tumour was not lost sight of,) and, considering that the former was not improbable, and that if it were the latter it could probably be safely dealt with by abdominal section, I proceeded to operate at 9 P.M. An incision about four inches long was made between the umbilicus and the pubes through the abdominal wall, and a piece of great omentum which lay beneath the incision and which was much matted together was first drawn out of the wound. The index finger of the left hand has then at once passed down to the obturator foramen, and there was no difficulty in detecting the fact that a portion of bowel was tightly strangulated in the upper part of the obturator foramen. It was quite impossible without employing undue force to draw this back, so a blunt-pointed bistoury was carefully passed down along the finger, and by directing the edge inwards the constricting ring was divided and the gut was reduced. The division of the stricture at such a depth from the surface and with the coils of ntestine surrounding the finger was a matter of some difficulty, but when it was accomplished the gut was drawn up with ease. It proved to be a part of the small intestine, about two inches long; it was of a bluish colour, but rapidly became red under observation. It was also seen that the previous traction had caused two slight rents in the peritoneal coat, which passed obliquely across the gut, the edges of which were accordingly drawn together with continuous sutures of very fine catgut. The lacerations bled readily. The portion of protruded omentum was then ligatured in two places and removed, the stump being returned, and the abdominal incision was approximated. The patient did not rally after the operation, though she took nourishment, including a good supply of brandy, well. The vomiting stopped, but her extremities remained cold and became more blue, and her skin was bathed in a cold perspiration. Towards the afternoon of the following day an excited delirium set in, and in the evening she died.

The autopsy revealed the fact that the portion of gut which had been constricted was about eighteen feet from the pylorus, and that its mucous membrane was dark and opaque from extravasated blood. There was slight peritonitis around the piece of gut which had been included in the hernia, the coils in this region being adherent to one another and to the pelvic wall by recent lymph. There was also a little reddish fluid in the peritoneal cavity. The hernial sac was of small size, and lay immediately beneath the pectineus muscle. Beyond considerable hypostatic congestion of the lungs, nothing else worthy of note was learnt from the post-mortem examination.

I do not wish to bring this case forward in order to advocate the method of treating obturator hernia by abdominal section in preference to the operation in Scarpa's triangle, though it is probable that the latter is a more difficult procedure. The abdominal section is not an altogether simple matter, and it no doubt involves certain risks which are not encountered in the other operation. It was selected in this case because the symptoms, while obvious enough to direct attention especially to the obturator region, were not thought to be clear enough to negative the possibility of the mischief being found in the locality to which the greater part of the pain had been constantly referred; and it was argued that if the latter had been the case, an abdominal section following the necessarily tedious operation in the thigh would have been a very serious matter in the exhausted condition of the patient. An important lesson to be learnt from the case is the extreme care which should be exercised in making traction on the intestine in a patient whose tissues, as they were in this case, are all in a very flabby and easily lacerable condition.

Wimpole-street, W.

WHAT IS THE EXPLANATION OF ACQUIRED IMMUNITY FROM INFECTIOUS DISEASES?

BY GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON, U.S.A.

IT is well known that in the specific infectious diseases of man and of the lower animals a single attack commonly confers immunity from subsequent attacks. There are, however, numerous exceptions to this rule, and the immunity conferred is not absolute, but has a variable value, which depends partly upon individual susceptibility, partly upon the physical vigour of the individual when subsequently exposed, and partly upon circumstances relating to the nature of the exposure—e.g., concentration of poison, mode of infection, &c. There is also evidence that in some cases at least the time which has elapsed since a first attack is an important factor in determining immunity when a subsequent exposure occurs. Even in small-pox and in yellow fever, diseases in which a single attack is in most cases protective during the lifetime of the individual, fatal second attacks occasionally occur. Nevertheless the general law of immunity as a result of a single attack is well established for a majority of the acute infectious diseases.

It is evident that the immunity which results from inoculation with an "attenuated virus"—as, for example, in Pasteur's protective inoculations against anthrax, or from vaccination—is of the same nature, and that a satisfactory explanation must include all established facts of this class. Upon taking a broad view of the question, it will be seen that it includes also the facts relating to relative race immunity, such, for example, as the comparative mildness of yellow fever in the negro, the alleged liability of the esquimaux to suffer a fatal attack of small-pox as a result of vaccination (Grawitz), the immunity of Algerian sheep from anthrax, &c.

Naturally this question has attracted the attention of the leading investigators in the field of experimental pathology, for its inherent interest and practical importance are apparent. Three explanations have been offered to account for the phenomena in question, which may be stated as follows:—(1) The "exhaustion theory," advocated by Pasteur, which supposes that some substance present in the body of a susceptible individual up to the time of a first attack, and which is essential for the development of the specific germ of the disease, is exhausted during the attack, and that consequently this particular germ is unable subsequently to multiply in the body of this individual. (2) The "antidote theory" advocated by Klebs and recently supported by Klein.[1] This theory supposes that some chemical substance is produced during the attack which is inimical to the development of the germ, and which, remaining in the body of the animal, prevents its subsequent development. (3) The vital resistance theory, which supposes that immunity is due to an acquired tolerance on the part of the living cellular

[1] Micro-organisms and Disease, Practitioner (London), vol. xxxiii, No. 4, p. 219.

elements of the body to the poisonous products evolved by disease germs, to which they probably owe their pathogenic power, and a consequent ability to resist invasion by them. According to this view individual and race differences in susceptibility, as well as the more or less perfect immunity resulting from a single attack of any one of the specific infectious diseases, are phenomena depending upon differences in vital resisting power, either inherited or acquired. The last-mentioned theory is referred to by Klein in his recent work on "Micro-organisms and Disease" in the following language:—"Some observers (Grawitz, &c.) are not satisfied with this theory" [the antidote theory], but assume that, owing to the first attack, the cells of the tissues so change their nature that they become capable of resisting the immigration of a new generation of the same organism. There is absolutely nothing that I know of in favour of such a theory; it is impossible to imagine that the cells of the connective tissues, of the blood, and of other organs, owing to a past attack of scarlatina, become possessed of new functions or of some new power—as, for instance, a greater power of oxidising, or the like."

As the present writer is perhaps included in the "&c." ("Grawitz, &c.") of the above quotation, he feels called upon to say something in favour of the theory thus summarily disposed of, which seems to him to be the only one thus far offered which is at all tenable, and which he advocated in an article published in the *American Journal of the Medical Sciences* of April 1st, 1881, which has the precedence over the paper by Grawitz by a few days, the latter having appeared in Virchow's *Archiv* on the 8th of the same month. In order that the two explanations which I reject as untenable may be fairly presented to the readers of the present paper, I shall quote verbatim the arguments advanced in their support by their most prominent advocates.

The first hypothesis (1) is supported by Pasteur in the following language:—"It is the life of a parasite in the interior of the body which produces the malady commonly called 'choléra des poules,' and which causes death. From the moment when this culture (i.e., the multiplication of the parasite) is no longer possible in the fowl, the sickness cannot appear. The fowls are then in the constitutional state of fowls not subject to be attacked by the disease. These last are as if vaccinated from birth for this malady, because the fœtal evolution has not introduced into their bodies the material necessary to support the life of the microbe; or these nutritive materials have disappeared at an early age. Certainly one should not be surprised that there may be constitutions sometimes susceptible and sometimes rebellious to inoculation—that is to say, to the cultivation of a certain virus, when, as I have announced in my first note, one sees a preparation of beer yeast made exactly like one from the muscles of fowls (bouillon) to show itself absolutely unsuited for the cultivation of the parasite of fowl cholera, while it is admirably adapted to the cultivation of a multitude of microscopic species, notably to the bactéride charbonneuse (bacillus anthracis). The explanation to which these facts conduct us, as well of the constitutional resistance of some individuals, as of the immunity produced by protective inoculations, is only natural when we consider that every culture in general modifies the medium in which it is effected; a modification of the soil when it relates to ordinary plants; a modification of plants and animals when it relates to their parasites; a modification of our culture liquids when it relates to 'mucédines,' 'vibrioniens,' or ferments. These modifications are manifested and characterised by the circumstance that new cultivations of the same species in these media become promptly difficult or impossible. If we sow chicken bouillon with the microbe of fowl cholera, and, after three or four days, filter the liquid in order to remove all trace of the microbe, and subsequently sow anew in the filtered liquid this parasite, it will be found quite powerless to resume the most feeble development. The liquid, which is perfectly limpid after being filtered, retains its limpidity indefinitely. How can we fail to believe that by cultivation in the fowl of the attenuated virus we place its body in the state of this filtered liquid, which can no longer cultivate the microbe? The comparison can be pushed still further; for, if we filter the bouillon containing the microbe in full development, not on the fourth day of culture, but on the second, the filtered liquid will still be able to support the development of the microbe, although with less energy than at the outset. We comprehend, then, that after a cultivation of the modified (*atténué*) microbe in the body of the fowl, we may not have removed from all parts of the body the aliment of the microbe. That which remains will permit a new culture, but in a more restricted measure. This is the effect of a first inoculation; subsequent inoculations will remove progressively all the material necessary for the development of the parasite."[2] In commenting upon Pasteur's explanation of acquired immunity in the chapter on "Bacteria in Infectious Diseases" in my recent work I remark:[3] "It is a little surprising that after disproving by the experimental method the hypothesis last mentioned"—viz., the antidote theory adopted by Klein—"which had been proposed by a member of the French Academy in explanation of the phenomenon in question, Pasteur did not, in accordance with his usual custom, attempt to establish his own hypothesis upon a firm foundation by an experiment which at once suggests itself. If a fowl which is protected against cholera, or an animal which is protected against anthrax, owes this protection to the fact that a certain material which is required for the development of the microbe of fowl cholera, or for the anthrax bacillus, has been exhausted in the course of the modified form of the disease to which immunity is due, then the flesh of such an animal made into bouillon should not constitute a proper culture medium for the organisms in question. The writer ventures to predict that the result of such an experiment would not be favourable to Pasteur's hypothesis, and that it will be found that the micrococcus of fowl cholera can be cultivated in bouillon made from the flesh of a protected animal, and that the bacillus of anthrax may multiply freely in the blood, or in an infusion of the flesh, of an animal which, before it was killed for the experiment, possessed immunity against the disease anthrax."[4]

Since the above was written, Salmon in the United States and Klein in England have reported the results of experiments which show that the prediction made was well founded.

Salmon says, in a recent communication to *Science*:[5]—"I trust, however, you will pardon me for calling your attention to the fact that more than two years ago I demonstrated that immunity was only relative, never absolute; that the most susceptible individual possessed a certain degree of immunity which can be accurately measured; and that all degrees of immunity may be overcome by a sufficient increase in the dose of virus. The immunity of the animal body, then, in no sense resembles the exhausted cultivation liquid in the flasks of Pasteur and Tyndall, which no increase in the amount of virulent material added can ever induce to support the development of new generations of the microbe, and the honour of demonstrating this radical difference is due to American investigations. I went further than this, however, and showed that this theory of our European friends was absolutely untenable, because broth made with distilled water from the flesh of an animal that had been granted a very complete immunity was just as favourable a medium for the growth of the virus as that made from susceptible animals; and that such virus lost nothing in virulence by being grown in such a medium. I will not trouble you with the theory of immunity which I developed from these experiments. Like other American work, it may have no value; but it may interest you to know that an able German writer, in the last number of Virchow's *Archiv*, has propounded a theory which in its most important points is identical with my own."

In referring to this theory as his own, Salmon seems to have overlooked the fact that I offered the same explanation of acquired immunity in my paper, already referred to, which was published in the *American Journal of the Medical Sciences* for April, 1881.

Klein says, with reference to the exhaustion theory:—"On careful analysis it will be found that it is not capable of explaining the facts of the case. As we mentioned in a former chapter, cattle inoculated with blood of a guinea-pig dead of anthrax become affected with anthrax, which, although not fatal, is nevertheless sometimes very severe. The animal recovers, and is now, for a time at least, secure against a second attack. But there is absolutely no ground for the assumption that if an infusion of the tissues of this animal were made the bacillus anthracis sown in it would not thrive luxuriantly, seeing that bacillus anthracis grows upon almost anything that has a trace of proteids. Similarly, when of the tissues of a guinea-pig, or mouse, or rabbit, dead of

[4] Op. cit., p. 245. [5] Sept. 26th, 1884, p. 303.

anthrax, an infusion is made, and this is used as nourishing material for bacillus anthracis in artificial cultures, it is found that these latter thrive splendidly. There is then no reason whatever for assuming that, after one attack of illness the blood and tissues become an unfavourable soil for a second invasion of the same organism, and that this change is due to the exhaustion of some necessary chemical compound."[6]

In my own paper, heretofore referred to, in the absence of experimental data I argue as follows:—"Let us see where this hypothesis leads us. In the first place, we must have a material of small-pox, and a material of measles, and a material of scarlet fever, &c. Then we must admit that each of these different materials has been formed in the system and stored up for these emergencies,—attacks of the diseases in question,—for we can scarcely conceive that they were all packed away in the germ cell of the mother and the sperm cell of the father of each susceptible individual. If, then, these peculiar materials have been formed and stored up during the development of the individual, how are we to account for the fact that no new production takes place after an attack of any one of the diseases in question? Again, how shall we account for the fact that the amount of material which would nourish the small-pox germ to the extent of producing a case of confluent small-pox may be exhausted by the action of the attenuated virus (germ) introduced by vaccination? Pasteur's comparison of a fowl protected by inoculation with the microbe of fowl cholera with a culture fluid in which the growth of a particular organism has exhausted the pabulum necessary for the development of additional organisms of the same kind does not seem to me to be a just one, as in the latter case we have a limited supply of nutriment, while in the former we have new supplies constantly provided of the material (food) from which the whole body, including the hypothetical substance essential to the development of the disease germ, was built up prior to the attack. Besides this, we have a constant provision for the elimination of effete and useless products. "This hypothesis, then, requires the formation in the human body, and the retention up to a certain time, of a variety of materials, which, so far as we can see, serve no purpose except to nourish the germs of various specific diseases, and which, having served this purpose, are not again formed in the same system, subjected to similar external conditions, and supplied with the same kind of nutriment."

It hardly seems worth while to give further attention to this explanation offered by the great chemist to whom we owe so much, but who, if we may judge from his reasoning in this instance, is not equally great as a physiologist. We proceed, therefore, to consider hypothesis No. 2.

(To be continued.)

REMARKS ON

NINE CASES OF DEATH BY HANGING

(SIX EXECUTIONS AND THREE SUICIDES).

BY R. J. KINKEAD, M.D. DUB.,

LECTURER IN MEDICAL JURISPRUDENCE, QUEEN'S COLLEGE, GALWAY.

IT has been my lot to have rather an extensive experience in death by hanging, both by execution and suicide; although the scientific value of such experience has been largely reduced by the want of post-mortem examinations in all the cases save one, yet something may be learned from a report of them. In the case of executions the prison surgeon has no power to make a post-mortem unless ordered by the coroner. On sentence of death being passed, the prisoner is remitted to the local prison whence he came, and given into the custody of the governor. He remains in his custody, subject to the special rules for condemned prisoners, until the day fixed for execution. The death warrant is in the meantime issued to the sheriff, who has charge of everything connected with the execution. He it is who provides the gallows and engages the executioner, who acts as his officer. The sheriff is not bound to engage the public executioner; he can arrange with anyone he likes. In case no executioner can be found the sub-sheriff is bound to act as executioner, and in case he fails or refuses the high sheriff himself must discharge the duty. On the morning fixed for the execution the sub-sheriff comes to the prison, presents the death-warrant to the governor, and demands the body of the condemned, who is handed over to his custody, and by him to the executioner. Thus the condemned passes from the custody of the prison authorities entirely, and neither the governor nor any prison officer can interfere with him any more. They are, however, bound to assist the sheriff in the discharge of his duty; and by Act of Parliament the governor or deputy governor, the chaplain, and medical officer of the prison must be present at the execution, and make certain statutory declarations. But once the body of the criminal has been handed over to the sheriff, he passes completely from under the custody and control of the prison officials. It is necessary that this should be clearly understood, as there is a general impression to the contrary, and if, as sometimes happens, an accident occurs during an execution, the prison officers are supposed to be accountable, and to have an interest in hushing it up. It cannot be too clearly understood that they have nothing whatever to do with an execution beyond assisting the sheriff and acting as witnesses, and that the entire responsibility rests with the sheriff. Under this mistaken idea of the prison officers' duty it has been urged that the post-mortem examination on the body of an executed criminal should not be made by the prison surgeon, but that on independent medical man should be present at the execution, and give evidence at the inquest. I am not aware that there is any law which authorises a prison surgeon to make a post-mortem examination, on either an ordinary prisoner or executed criminal, without the requisite permission either of the relatives in the former case, or of the sheriff in the latter; and I am not certain whether the sheriff, although the legal custodian of the body, can give permission. He is debarred from the power, given to those in custody of a dead body by the Anatomy Act, of giving it for anatomical purposes. Consequently in cases of executions I have been unable to make a post-mortem examination, unless by order of the coroner. The body having passed to the custody of the sheriff I have felt I had no power as a prison officer to interfere with it. In the case of suicides, in addition to the difficulty likely to arise from the necessity of obtaining the permission of the relatives, the prison surgeon is prevented from making a post-mortem examination even at the coroner's bidding by an order from the executive; that in the case of any prisoner dying in prison, the post-mortem examination, if directed by the coroner to be held, shall not be made by the prison surgeon, but by an independent medical man, to be called in by the coroner for that purpose. This raises a question of law. In private practice, if an inquest is necessary, it is inexpedient that the medical attendant should make the post-mortem examination if any possibility of any question concerning the treatment could arise. In the case of a prisoner dying in prison an inquest must be held, and as the question of treatment, both medical and otherwise, necessarily arises, it is obviously expedient, unless the cause of death is very clear and the proof of good treatment convincing, that a post-mortem examination should be made, and that the duty should be discharged by "an independent medical authority." But as matters stand, the medical officer may be placed between the hammer and the anvil. The coroner is not under the authority of the executive. He is an independent judge, and can refuse to receive orders either from the Home Secretary in England or the Lord Lieutenant in Ireland. Suppose he orders the medical officer to make a post-mortem examination: if the surgeon obeys the coroner, he must disobey his superior officers; if he refuses to make the post-mortem examination, the coroner can commit him for contempt of court.

Shortly after the circular was first issued the coroner of the city of Dublin refused to recognise its authority, and directed the medical officer to make a post-mortem examination on the body of a criminal executed for murder. The Royal Commission on Prisons in Ireland has recommended that "governors be requested, whenever an inquest is about to be held, to inquire of the coroner whether a post-mortem examination is to be made, and, if he should reply in the affirmative, to inform him that" the Lord Lieutenant "wishes such examination to be made by a medical practitioner not connected with the prison service." This mode would certainly be an improvement; it would prevent the medical officer being placed in the very awkward predicament of having to choose which authority he should obey; and there are few coroners who would refuse to comply with a request

[6] The Practitioner, London, Oct. 1884, p. 247.

so conveyed. In only one case of the nine I have seen did the coroner deem a post-mortem necessary. Since January, 1880, there have been ten men executed, and three have committed suicide by hanging in Her Majesty's Prison at Galway. I have been present at the execution of six of these men, and saw the bodies of the suicides within a few minutes of their being discovered.

In eight of the executions Marwood was the hangman, and although he discharged his duty with celerity and death was instantaneous, yet it seemed to me that the time must have appeared terribly long to the criminal from the commencement of the preparations until the bolt was drawn. My observations have also convinced me that in no case should one executioner attempt to hang more than one person at a time; for not only is it likely that an accident may result—as actually did happen in one case—and the death of the criminal be prolonged, but the mental strain and agony of the miserable criminal waiting on the drop until the others are prepared must be something awful. To me, standing looking on, the time seemed interminable, although the work was done rapidly and did not occupy more than a minute or two. What must it have been to the unfortunate creature on the brink of eternity! This will be fully understood from a description of the process. The prisoner's arms are pinioned in the condemned cell. A belt is buckled round the waist; to this belt are attached two straps, which, when the belt is in its place, are about an inch or two in front of and above the anterior superior spine of the ilium. The arms are fastened to the side of the belt by these straps, so that the fingers can barely cross in front, and the elbows project somewhat behind. The pinioning being effected, the prisoner is marched to the scaffold and placed on the drop, immediately under the ring in the cross-beam, to which the rope is attached; the legs are then fastened together by means of a strap placed between the knees and the ankles. Next, the noose is placed round the neck, drawn firmly round the throat, and kept in position by a washer or ring. The white cap is then put on, and the executioner, stepping back, pulls the bolt. Now, it is evident that, no matter how dexterous and practised the executioner may be, the strapping the legs, adjusting the rope, and putting on the cap must take time; and if the prisoner is left standing while the same thing is being done to one or two others, his suffering must be very terrible. What it actually is I suppose no one can conceive; but in one case, although a single execution, and done very quickly, the man fainted, and was actually falling sideways when the bolt was drawn.

In Marwood's executions he used the long drop, and placed the knot under the chin. The rope hung down behind the prisoner's back from the ring in the cross-beam, and looped up from below the waist to its attachment under the chin. Thus it will be seen that the length of the drop was something more than the prisoner's height. This arrangement worked well if the prisoner was steady; but if restless, then there was the danger of what actually happened once—of the loop of the rope catching the convict's elbow as the body fell, and so preventing death being instantaneous. The first man I saw hung was executed in Jan. 1880. He was a tall, powerfully-built fellow, and met his death with great fortitude. One hour and a half after the execution, assisted by Dr. Pye, professor of anatomy, I made a post-mortem. Fæces had not been passed, but there had been an emission of seminal fluid. On dissecting the neck, we found most of the tissues torn through, the body of the third cervical vertebra was broken diagonally across and separated for at least two inches and a half to three inches from the remaining portion, the spinal cord was torn through, and in fact the head was retained in connexion with the trunk merely by the skin, which was not even abraded, a few muscular shreds, and the vessels on the right side. The trachea and œsophagus, the carotid artery and jugular vein on the left side, were torn through, and the tissues were emphysematous. On opening the thorax, nothing particularly abnormal was discovered in the lungs; they were slightly congested, but not to a very appreciable extent; the left heart was empty and firmly contracted, but on the right side both auricle and ventricle were full of frothy blood, the air escaping from the ruptured trachea having been evidently sucked down through the jugular vein.

The next execution I witnessed was in January, 1883. The prisoner walked with tolerable firmness to the scaffold, but appeared to faint on it, for just as the bolt was pulled he fell sideways towards the left; the drop too was evidently a very long one, as the loop of the rope was below the level of his knees. To ascertain roughly the lesions producing death did not need a post-mortem, as all the tissues, save about from one and a quarter to two inches of skin on the right side of the neck, were entirely severed. In fact, had it not been for that small portion of skin he would have been completely decapitated. I attribute this result to an excessively long drop, to a thin neck, and to a rotary motion being imparted by the man's fainting, so that the pull on the body falling did not act in the line of the long axis of the neck, but partly laterally. The next two men were executed two days after. The coroner did not deem a post-mortem examination necessary, but, from an external examination, I have no doubt that the bones of the vertebræ were separated in each case. In the first case I have recorded there was actual fracture of the body of the third cervical vertebra; in the second case the separation took place between the bodies of the second and third cervical vertebræ; and, as far as I could judge in the last two, luxation was about the same place; the ends of the bodies of the vertebræ could be distinctly felt separated from each other by at least two inches and a half.

If I recollect rightly, the evidence in the Dublin executions was to the effect that in all cases the vertebral bones were torn apart and the spinal cord severed. In the four cases which occurred while I was absent from Galway no post-mortem was made, but the gentlemen who discharged my duty have informed me that they had no doubt as to separation of the bones in three. In the fourth, the case in which the rope caught under the elbow, the doctor's evidence at the inquest was that there was no dislocation or fracture of the neck, and that death resulted from strangulation.

(To be continued.)

A CASE OF

HIGH AMPUTATION FOR GANGRENE OF THE FOOT; OBSTRUCTION OF THE POPLITEAL ARTERY BY HYDATID CYSTS.

BY H. MALLINS, A.B., M.B., M.CH.

JOHN T——, aged seventy-four, a labourer, always enjoyed good health until about seven years ago, when, owing to some slight injury, an ulcer formed on the anterior aspect of the middle third of the left leg. This ulcer seemed always to have been extremely painful, and for its relief, according to his account, every remedy, orthodox and unorthodox, had been tried without avail. At the end of last summer, the pain having become more severe, owing to a sloughing tendency which the ulcer began to exhibit, he was admitted into the Norwich Hospital, where he remained several weeks. Under the treatment adopted great improvement followed, and at the time of his discharge the ulcer was all but healed. A few weeks later, however, the whole foot of the affected side began to show signs of disease, the ankle became œdematous, and several of the metatarso-phalangeal joints suppurated and discharged. This recrudescence of the disease was attended with great suffering, the climax of which was reached at the beginning of January, when gangrene of the great toe showed itself. Amputation of the limb was now proposed, and, the risks of the operation having been duly explained, eagerly assented to. The operation was performed under chloroform on January 11th, by the method of long anterior and short posterior flaps, the femur being sawn through at the junction of the lower and middle third. On applying the tourniquet no pulsation of the femoral artery could be detected. Subsequently, when the fleshy parts were divided, the artery was found to be completely plugged by a firm clot. The collateral circulation seems to have been pretty well established, as six vessels required ligature. The wound having been well cleansed with dilute carbolic solution, a dressing of plain absorbent wool was applied. Everything proceeded favourably for the first forty-eight hours, when the temperature began to rise. On dressing the wound the anterior flap was found to have commenced to slough. Gangrene of the entire stump rapidly ensued, with a fatal result on the fifth day.

On examining the vessels of the amputated limb, the popliteal artery was observed to be much enlarged, presenting a fusiform dilatation, about an inch wide and four inches in length. In the process of dissection, the swelling having been accidentally pricked with the knife, a white matter, suggestive at first sight of pus, spurted out. On laying the swelling open, however, no pus could be detected. The walls of the artery were found to be thickened, but the main bulk of the dilatation was constituted by its contents, which consisted of a mass of hydatid cysts, varying in size from that of a very small pea to that of a good-sized raisin. Their walls in every case were collapsed. No hooklets could be discovered with the microscope. To clear up any doubt as to their true nature, a few specimens were sent to Dr. T. Spencer Cobbold, who most kindly examined them, and expressed the opinion that "they are unquestionably true hydatids. The ectocyst displays well-marked characteristics appertaining to echinococcus veterinorum."

Remarks.—It was the paper of Mr. J. Hutchinson, read before the Royal Medical and Chirurgical Society on Dec. 11th, 1883, urging the safety and expediency of high amputation in senile gangrene, that led to the undertaking of the operation in the foregoing case. It had been originally intended to amputate at the knee, but the existence of a small purulent depôt close to the popliteal space led to a suspicion of the healthiness of the tissues in its vicinity. One point to which it is desired to call attention is the early sloughing of the anterior flap. The experience of St. George's Hospital is, according to Mr. T. Pickering Pick, decidedly adverse to long anterior flaps, sloughing having taken place sixteen times in twenty-nine cases. The skin of a man aged seventy undergoes a certain amount of atrophy, a process in which its nutrient bloodvessels doubtless share. In the formation of a skin flap numerous vessels going to it must be divided, thus diminishing its vitality. Moreover, it is not improbable that a slight sloughing is quite sufficient to start off the process of gangrene afresh. For the foregoing reasons the method of long anterior flaps would seem to be unadvisable in amputation for senile gangrene. Though hydatids are found in many different situations in the human body, they seem to take up their abode in the bloodvessels but very rarely. In M. Davaine's analysis of 373 cases of hydatids, as given in Dr. T. Spencer Cobbold's work on "Entozoa," two cases occur in which the pulmonary vessels were the site of the cysts. As far as I can ascertain, these are the only cases of the kind hitherto recorded. In conclusion, it may be pointed out that there was very probably some connexion between the chronic ulcer of the leg and the plugging of the popliteal artery; either diminished blood-supply or pressure on the nerve from the bulging of the artery, leading to diminished vitality of the affected part. The constant and very severe pain would indicate the latter as the more probable cause.

Watton, Norfolk.

NEW REMEDY FOR CHOLERA.

BY SHAMSUDIN J. SULEMANI, L.M. BOMBAY.

DURING the latter part of the epidemic of cholera, which broke out in July last at Baroda (a town in India), five marked cases of this disease were treated with jadvari khatai, papita, narjili daryai, and cardamom seeds; four of these were cured and one proved fatal. The above-mentioned four drugs were mixed and given in ten-grain doses to adult patients every hour or two, according to the severity of the symptoms; in each case three or four doses were used. The following are the notes of the cases in question:—

CASE 1.—A girl of about twelve was attacked with cholera at 1 A.M., and seen by me at 6 P.M. the same day. Her body was cold, pulse almost imperceptible, eyes sunken, frequent purging, stools watery and copious, and of the colour of rice water. There was suppression of urine of twelve hours' standing. Before I saw her she had been given chlorodyne and stimulants, but without any effect. Three doses of the above medicine were administered to her, the second dose being given one hour after the first, and the third after two hours. Soon after the administration of the first dose purging diminished and the pulse became perceptible; the second dose was followed by marked improvement, and the extremities and the trunk became gradually warm. She voided urine some two hours after the third dose, and was then out of danger.

CASE 2.—An adult male commenced purging and vomiting at 6 A.M., and was treated with chlorodyne and stimulants, but without relief. I saw him at 5 P.M. the same day, and found him much exhausted. His eyes were sunken, extremities cold, and pulse hardly perceptible. Vomiting was incessant, and he could scarcely retain medicine or water, and had cramps. He had not passed urine for about eight hours. Sinapism to the epigastrium did not check vomiting, and so a mixture of equal parts of laudanum and chloroform was sprinkled over a piece of lint, which was applied over the pit of the stomach for about five minutes, though not continuously, and it stopped the vomiting. Immediately after this the medicine above referred to was given, and he gradually improved. It was repeated twice at the interval of two hours, and he passed urine and recovered.

CASE 3.—A woman aged twenty-five began to vomit and purge at 6 P.M., when chlorodyne and some other medicine were administered, by which vomiting was checked, but purging continued unabated. The next morning, at 11 A.M., I was called to see her for the first time. She was not able to speak, but could open her eyes when shouted to. She had not passed urine since the attack commenced. The whole body was cold, and there was no pulse; even the beating of the brachial artery could not be felt. Now and then cold perspiration broke out. Two doses of the above medicine were given, but there was no effect. Subsequently some other treatment was adopted by another medical gentleman, but the patient died at about 5 P.M.

CASES 4 and 5.—The remaining two cases had well-marked symptoms, and showed signs of improvement after the first dose; they were ultimately cured by two subsequent doses in one case, and by three in the other.

I may observe here that in all these five cases no food was allowed while vomiting and purging continued. Sinapism to the epigastrium (for checking vomiting) and friction and warm bottles to the extremities were ordered. As regards the medicinal properties of the above-mentioned drugs, I beg to state that the first three are said to be tonic, and recommended in Makhzanuladviya for cholera; cardamom seeds act simply as carminative. Their botanical names and the natural orders to which they belong are as follows:—

Name of drug.	Botanical name.	Natural order.
Jadvari khatai.	Delphinium denudatum.	Ranunculaceæ.
Papita.	Strychnos ignatii.	Loganiaceæ.
Narjili daryai.	Lodoicea seychellarum.	Palmeæ.
Cardamoms.	Elettaria cardamomum.	Zingiberaceæ.

These drugs are mentioned by Dr. W. Dymock in his "Vegetable Materia Medica." Narjili daryai has a very hard kernel, and requires to be filed before it is finely powdered.

It is obvious that the number of cases in which this new remedy was tried is too small to enable one to judge of its value; however, it deserves a further trial.

Oxford.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas at morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Procemium.

ST. GEORGE'S HOSPITAL.

EIGHT CASES OF FRACTURE OF THE PATELLA, PUT UP IN GUM BANDAGES AS SOON AFTER THE ACCIDENT AS POSSIBLE; REMARKS.

THE following cases illustrate the method of treatment of fracture of the patella as at present practised at one of the large London hospitals. It comprises the essentials of treatment of such fractures—rest, relaxation of the quadriceps extensor of the thigh, and apposition of the fragments by direct pressure. It also permits the patient to get about at an early date after the injury, the fractured ends being still retained in good position, and the knee-joint kept extended by means of the gum bandage. We would also refer to the

remarks appended to Mr. Rivington's case, where suppuration followed paracentesis of the joint, in a case of simple fracture of the patella.[1]

For the report of the following cases we are indebted to Mr. Allingham, house-surgeon.

CASE 1. (Under the care of Mr. Holmes.)—Thomas S——, aged thirty-five, carman, was admitted on Sept. 7th with the following history. While walking along the street he slipped off the kerb, and in trying to save himself from falling under his van heard something give way with a snap. Attempting to rise, he was utterly unable to use his left leg, so he was brought to the hospital. On admission the left patella was fractured transversely about its middle, the fragments being separated one inch; there was very little effusion into the knee-joint. It was immediately done up in the following manner. The limb having been thoroughly washed, the fragments were brought together with ordinary strong strapping. The centre of a piece of strapping one inch and a half wide, and long enough to encircle the limb twice, was placed immediately above the upper fragment, and the two ends pulled in the direction downwards and backwards, crossed behind the joint, and brought forward to meet upon the tubercle of the tibia. This tends to bring the upper part of the patella down to the lower. The other fragment was treated in like manner; a similar strip of strapping was placed just below the lower fragment, then crossed behind the joint and made to meet above the patella in front of the thigh. Next, strapping, two inches and a half wide, was placed over the front of the patella, each end drawn forcibly backwards, crossing behind the joint, brought forwards again, so that the ends might stick on the front of the knee. (Great care must be taken that none of the strapping slips in the slightest degree.) The limb was then well starched and covered evenly from the level of the base of the little toe to about two inches below the perineum, with two thicknesses of flannel bandage, and this in a similar manner encircled by a coarse muslin bandage three inches in width, strong thick gum being then spread over this. Two more layers of bandage, alternating with two of gum, having been applied, the splint was completed. During this process—or after the fragments were brought together with strapping—the leg was supported by the heel, nothing being placed under the thigh or knee that might tend to bend the joint in the slightest degree; for it is absolutely necessary that the fracture be not disturbed, and that the gum bandage should dry with the leg in a state of extreme extension. During the drying the leg was raised by a block placed under the heel to prevent the wet bandage sticking to the bed; as soon as the outside dried, the limb was placed in a patella junk. (The outer layer of gum takes about four hours to dry, but two days are required for the splint to become firm and hard.)

Sept. 8th.—Splint is drying fast, being elevated in a patella junk. Patient complains of pain in the knee; the toes are not swollen. Temperature normal; pulse 80; tongue clean and moist. Did not sleep well.

10th.—Still complains of a little pain, but much less than it was. Temperature normal; slept well.

14th.—No pain; got up and walked about the ward with the help of crutches.

21st.—Left hospital, fourteen days after the accident.

The patient returned about the middle of October, the splint being quite comfortable. He was told to come back at the end of three months, when the splint will be removed and a leather knee-cap supplied him.

CASE 2. (Under the care of Mr. Holmes.)—William B——, aged thirty-five, a painter, fell five feet and fractured his patella transversely by indirect violence on October 30th. On admittance, the fragments were separated about one inch. The accident occurring near the hospital, he was seen about ten minutes after, and as there was no effusion, the fractured surfaces were brought together with strapping as described in Case 1, and the limb enveloped in a gum bandage.

Oct. 31st—Had a good deal of pain in the knee, which was much relieved by elevation.

Nov. 1st and 2nd.—Still some pain, but not so severe; temperature remained normal; toes warm and not blue or swollen.

6th.—Patient was up but had not put his foot to the ground.

12th.—He left the hospital, thirteen days after the accident, with orders to return in a month.

Dec. 15th.—The splint becoming loose, it was removed. The fracture was in good condition with a quarter of an inch between the fragments. Another splint was then applied and he was told to come back at the end of January for a knee-cap.

CASE 3. (Under the care of Mr. Rouse.)—Arthur M'——, aged forty-six, was brought to the hospital on May 24th with the following history:—Whilst running he slipped on a stone, and, trying to save himself, felt something give way in his knee. The right patella was found fractured transversely, the fragments separated about an inch and a half to two inches, with some effusion into the knee-joint. As this was not considerable, and as the upper and lower fragments of the patella could be placed in good apposition, the limb was put up immediately in gum bandage as described in Case 1. For a few days he complained of pain in the joint, but as he was able to sleep and eat, and as his temperature remained normal, it was not deemed necessary to remove the splint. The pain in this case was greatly relieved by well elevating the limb. On June 2nd he left his bed and was about the ward, leaving the hospital on June 6th, thirteen days after the accident, with orders to come up to be seen every month. In July he presented himself and urged to have the splint removed, as he felt confident the leg was well. This was done, and the upper and lower fragments were found in very good position, firmly bound together with an interval of one-third of an inch. He was ordered a leather knee-cap.

CASE 4. (Under the care of Mr. Rouse.)—Sarah D——, aged thirty-four, pregnant seven months, was admitted on April 28th. While descending some stairs she caught her foot in the carpet and fell down. The left patella was found fractured transversely; no effusion into the joint, fragments separated about three-quarters of an inch, but easily approximated so as to elicit bony crepitus. The joint was strapped and the gum bandage applied at once. That night, and for the next few days, the patient complained of pain, which was greatly mitigated, as in the former, by elevation of the limb.

On May 6th she was about the ward, and left the hospital on the 8th, ten days after the accident. This patient has not been to the hospital since.

CASE 5. (Under the care of Mr. Pick).—Sarah MacP——, aged sixty, while walking along the street fell and struck her knee against the pavement. She was immediately taken home and fomentations ordered by her medical man. On June 29th, seven days after the accident, she came to the hospital. The left patella was fractured obliquely, the line of fracture running from without upwards and inwards, the fragments separated one inch. There was a large quantity of fluid in the joint, and great bruising extending over the front and sides of the joint, spreading also down the leg. Under these circumstances it was not thought advisable to treat this case as those previously described. So the leg was bandaged, including the knee, with a Martin's bandage, as tightly as the patient could bear it, the leg elevated, and an ice-bag placed over the joint. At night she complained of so much pain as to necessitate loosening the bandage, the ice being continued. This treatment was pursued for six days, when all the excessive fluid was found absorbed, and the fragments could be drawn together; the leg was put up in the usual way. She left the hospital on July 23rd, three weeks after admittance.

At the end of September, three months after the accident, the splint was removed. The fragments were in good position, with about one-third of an inch interval; but, as the bond of union was not strong, she had the splint reapplied for another month before commencing to wear a knee-cap.

CASE 6. (Under the care of Mr. Haward.)—Rose W——, aged thirty-nine, married. Two days before admittance into hospital she fell from some steps, and in trying to save herself injured her right patella.

On admission, Feb. 14th, a transverse fracture was found with one inch interval between the fragments, and no effusion into the joint. The fractured bone being placed in a good position, the leg was enveloped in the gum bandage.

Feb. 15th, 16th, and 17th.—Leg quite comfortable; no pain.

18th.—She got up, leaving the hospital on Feb. 27th, a fortnight after the accident.

May 14th.—The splint was taken off. A firm, strong, fibrous band, uniting the fracture with a quarter of an inch between the fragments, existed. Knee-cap ordered.

CASE 7. (Under the care of Mr. Haward.)—Walter C——,

[1] THE LANCET, Jan. 24th, p. 154.

aged thirty-three, carpenter. Slipped, catching his foot in a carpet. In falling he heard his knee-cap break. He could not stand, so was brought to the hospital on Feb. 19th. Right patella was fractured about its middle, with an inch and a half interval. As there was no excess of synovial fluid in the joint, the leg was put up at once.

Feb. 25th.—Had been up two days, going out on Feb. 27th, eight days after the accident.

On May 19th the gum bandage was removed. Good union and close apposition of the fragments being found, a knee-cap was ordered.

CASE 8. (Under the care of Mr. Haward.)—On March 17th Charles W——, aged thirty-two, drayman, was brought with the following history—viz., that he fell while walking on glazed tiles. On admission the left patella was found fractured, the fragments separated widely, nor could they be seen owing to the amount of fluid in the joint. This evidently was a case for the use of Martin's bandage, applied as in Case 5. After three days of this treatment the fluid was absorbed and the leg encased in gum bandages. The patient got up on March 23rd, and left the hospital on the 25th, eight days after the accident. The splint was taken off on July 2nd, and the fragments were found united by a firm and thick fibrous band, and separated half an inch.

Remarks.—With regard to this method of treatment, there are some points worthy of observation. It is well known that bringing the upper and lower parts of a fractured patella together tends to tilt the fragments so that the posterior edges of the fractured surfaces meet only, leaving an interval between the anterior edges. Now, it is to remedy this displacement that the third piece of strapping is used, the object being to press on both pieces, and so overcome the tendency to tilt. The amount of fluid in the joint is the indication for the method of treatment to be adopted. If the effusion is great, a Martin's bandage should be used for the first few days. On the other hand, a fracture accompanied with no increased secretion of synovia should be done up at once, for if left for only three or four hours there is sure to be considerable swelling. Previous to putting the fracture up in gum bandage it should be borne in mind, after the strapping is applied, to cover the limb in a double thickness of flannel bandage; for, as this is slightly elastic, it allows the leg to swell to a limited extent. Care should be taken, when putting on the muslin bandages, not to apply them too tightly, and as soon as the gumming is finished to elevate the limb. For two or three days after completion of the splint special attention should be paid to the temperature; if this remains normal, the tongue moist, and the toes warm, there is no need of alarm if the patient complains of pain; but should, on the other hand, the temperature rise, or the toes become swollen, cold, or blue, the splint must be immediately removed.

In treating these cases in the manner described quite as good results are obtained, with no more danger to limb or life and with the following advantages. The patient is not confined to bed for six weeks or two months, as he is if treated by Malgaigne's hooks or any other form of apparatus generally used, but can, as a rule, after a few days, say fourteen at the most, go home and undertake any light work. By strapping the fractured surfaces together and not interfering with them for three months it must be apparent that there is more probability of obtaining firm and good union than by those methods of treatment where it is necessary that the fracture should be frequently attended to, and the fragments thereby be more often disturbed; and certainly the method described is much less distressing to the patient. Putting up the leg in gum bandages rather than plaster-of-Paris has these advantages—viz., the splint is much stronger, does not bend or crack as plaster is apt to do, and, lastly, it is a much lighter apparatus.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.

CANCER OF THE RIGHT KIDNEY; CONGENITAL ABSENCE OF THE LEFT; NECROPSY; REMARKS.

(Under the care of Mr. F. E. MANBY.)

FOR the following notes we are indebted to Mr. J. W. Batterham, house surgeon.

George W——, aged forty-eight, a painter, was admitted on December 11th, 1884. The patient was a sallow, delicate-looking man, and suffered from dyspeptic symptoms. He stated that for fifteen years he had experienced pain in the right loin, that eighteen months ago he first noticed blood in his urine, and that five months ago his urine was again bloody, this time for three days, but since then he had had several attacks of hæmaturia at irregular intervals. He had lost flesh considerably during the last eighteen months. On the day of admission the urine contained a large quantity of blood and disorganised clot. No cells likely to be of malignant origin were found on microscopical examination of the urine. On passing a sound into the bladder no stone or tumour could be detected, nor was there any blood in the urine after the sounding. Examination of the abdomen revealed a smooth ovoid elastic tumour in the right lumbar and iliac regions, extending slightly into the umbilical region; its rounded margin could be distinctly felt on three sides, but above it appeared continuous with the liver at the level of the ninth rib. The tumour followed the descent of the liver and diaphragm on deep inspiration, and receded with them during expiration. The manipulation of the tumour was followed by the appearance of a little blood in the urine. The question of operation was entertained, but the patient was unwilling to submit to any operative interference. Meanwhile he caught cold, and died of bronchopneumonia.

Post-mortem examination showed the right kidney symmetrically enlarged, but presenting several small hemispherical bosses on its surface. It measured six inches by four inches and weighed twenty-five ounces. On section it was found to be infiltrated by a mass of encephaloid cancer. It contained no calculi or other concretions. Though a careful and prolonged search was made, no vestige of the left kidney and ureter could be discovered; nor could any trace of the left renal vessels be found, except a slight dimpling of the inner surface of the aorta at the spot where the renal artery would normally have been given off. On further dissection, it was found that the left vesicula seminalis was also absent, although the vas deferens pursued a perfectly normal course. Both testicles and both adrenal bodies were present and normal in appearance. No other abnormalities than those above described were discovered. There were no secondary deposits of the malignant growth. There were no adhesions between the liver and kidney, nor any apparent deficiency of perinephritic fat by which the mobility of the renal tumour might have been accounted for.

Remarks by Mr. MANBY.—The mobility of the tumour was a perplexing element in the diagnosis of the case Dr. W. Roberts states, with reference to renal cancer that the "fixity of the growth is usually a marked characteristic"; and had there been no hæmaturia, as happens (according to the above authority) in nearly half the cases of cancer of the kidney, the tumour would in all probability have been diagnosed as of hepatic origin. The absence of any other ascertainable cause of hæmaturia, and the appearance of blood in the urine immediately after manipulation of the abdominal growth, indicated, however, the nature of the case. The presence of one kidney only, illustrates one of the dangers of nephrectomy—viz., that of removing an only (or the only serviceable) kidney—an error which should be avoided by the use of Mr. Davy's rectal lever as a diagnostic instrument. By compression per rectum of the ureter of the kidney it is proposed to remove the flow of urine from the other ureter into a previously emptied bladder, as is readily demonstrable. This means of diagnosis has been successfully employed by Mr. Davy and others; and I have satisfied myself, by experiments on the cadaver, that the rectal lever will effectually control the passage of fluid along the ureter.

RUPTURE OF THE LUNG AND (?) RUPTURE OF THE LIVER; RECOVERY; REMARKS.

(Under the care of Mr. KOUGH.)

The notes of this case are also furnished by Mr. Batterham.

Eli T——, aged six years, was admitted on Dec. 21st, 1884, having been run over a few minutes previously by a light waggon, two wheels of which were said by a bystander to have passed over the patient's chest. He was sensible, but pale and collapsed. The pulse was small, quick, 168 per minute; respiration was abdominal, short, shallow, 76 per minute. Two hours after admission, when the effects of the shock were passing off, the following notes were taken. "Pulse 160; respiration 72. The short respiratory movements are restricted to the abdomen and left side of the chest. The little patient lies on his right side, with his thighs flexed on the abdomen, and complains of pain, which he locates when asked by placing his hand just above the umbilicus.

He has passed urine, which has been tested and found normal; and he feels sick. There are no broken ribs. The chest is distended; the right side is motionless, and the left nearly so. The whole chest is hyper-resonant, the liver dulness being completely lost. The breath sounds are exaggerated on the left side, and of a distant amphoric character on the right side. The tinkling bell sound which can sometimes be elicited on auscultating a case of pneumothorax is absent. There is a bruise over the right hypochondrium, and tenderness on pressure in the same region, but very little tenderness over the other parts of the abdomen. In the patient's present position (right lateral decubitus) abdominal percussion shows dulness on the right half of the belly, transgressing the median line. On turning the patient on to his left side the dulness changes its position to the left side, the dulness, however, remaining in the extreme right flank." As the administration of opiates seemed contraindicated by the embarrassed condition of the patient's breathing, no drugs were administered. He was kept lying on his right side, and carefully watched. By the 23rd his condition had improved. He had no longer the slight duskiness of the face. Pulse 136; respiration 44.

Dec. 25th.—The patient now lies on his back; both flanks are dull. The right side of the chest is less in circumference than the left, and moves less freely.

26th.—Liver dulness is not appreciable in the right nipple line. The patient feels better, has no pain, and wants to sit up in bed.

28th.—Respiration still less marked on the right side; no abdominal tenderness.

The patient was kept in bed until his discharge, at his parents' request, on Jan. 8th, 1885. He had manifested no jaundice, and his stools had been of normal colour.

Remarks by Mr. KOUGH.—This case is of some interest as illustrating not only the possibility of the occurrence of extreme pneumothorax from compression of the chest without fracture of the ribs, but the readiness with which this condition is remedied by nature without aid from the surgeon. Le Gros Clark in "The Diagnosis of Visceral Lesions," remarks that he has never found it necessary to perform paracentesis for this condition, and does not remember that it was ever so performed at St. Thomas's Hospital since his connexion with that institution. With reference to the injury to the liver, the absence of jaundice, of bilious stools, and of any marked signs of peritonitis (though this need not necessarily have been general or severe), tends to disprove the existence of any extensive laceration of the liver. On the other hand, physical signs showed the presence of a large quantity of fluid in the abdomen. This fluid could not, from the negative symptoms, have been derived from the intestines, bladder, or kidneys, and we are thus limited to the liver and spleen in our search for its presumed source. The reasons for assuming that the liver rather than the spleen was the source of the fluid in the peritoneal cavity are as follows:—1. The greater frequency of hepatic lesions due presumably to the greater fixity and bulk of the liver. 2. The presence of external marks of injury in the region of the liver. 3. The presence of tenderness over the liver, with a corresponding absence of extreme tenderness in the splenic region.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Violet Pigment discharged from the Mouth.—Atrophy of the Liver.—Rupture of Aorta.—Deposit of Bone in Testis.—Thrombosis of Vena Cava and Primary Sarcoma of Adrenal.—Congenital Sarcoma of Testis.—"Red-Water."

AN ordinary meeting of this Society was held on Tuesday last, Dr. J. Syer Bristowe, F.R.S., President, in the chair.

Dr. DICKINSON showed a handkerchief stained with Violet Pigment discharged from the Mouth. The case was that of a lady sixty years of age. Accidental introduction of pigment appeared to be out of the question. False teeth were worn on the side of the mouth from which the pigment was discharged. The tongue, on the right side, was coloured with the same vividly blue colour; there was no doubt that the pigment was derived from an aniline blue pencil, but there appeared to have been no deception practised by the patient. The discovery of the nature of the pigment was due to Dr. Paddison of the Surrey Lunatic Asylum; and Dr. Tindale, under whose care the patient was, subsequently detected a fragment of the blue pencil in the false teeth which the patient wore.—Mr. STEPHEN PAGET mentioned a somewhat similar case in which the half of the tongue was discoloured also from an aniline blue pencil.—Dr. RADCLIFFE CROCKER referred to a case in which a lady every time she washed her hands noticed that the soapy water became of a blue colour; this turned out to be due to the presence of some minute leaves of an orchid which were wafted unseen into the water.—Mr. PEPPER thought there was nothing extraordinary in the presence of aniline dyes in handkerchiefs.—Dr. BRISTOWE spoke of a case in which the linen of a lady became brown; this was not due to hair-dye but to a notorious hair-wash. Mention was made of a case in which a foreign body was passed from the bowel of a female; the body was of fusiform shape and transparent, and had a tail-like end. It proved to be the pulp of an orange.

Dr. CARRINGTON exhibited a specimen of Atrophy of the Liver, which might, however, have been one of acute cirrhosis. The patient, aged twenty-three, was a man, admitted on Nov. 13th, 1884, into Guy's Hospital, under the care of Dr. Goodhart. He had drunk, at least, eight pints of beer and some whisky every day for some weeks past. There was no history of gonorrhœa or syphilis. About two weeks before admission tremors appeared, great weakness set in, and the eyes became yellow. The body was well nourished; the mind was obscured; and the patient answered "No" to every question that was put to him. The respiratory and circulatory systems were normal; the liver dulness reached from the sixth rib in the mammary line to the lower border of the thorax; the urine was dark, acid, and contained no bile or albumen. After a time vomiting supervened, and the patient became more and more stupid, and finally delirious. Five days after admission epileptiform convulsions set in, and the seventh of these proved fatal. At the autopsy the body was well nourished; the conjunctivæ were slightly jaundiced; there was nothing abnormal found in the contents of the head; the lungs showed some hæmorrhagic patches, which ranged in size from a hazel-nut downwards; the heart was healthy, the left ventricle being firmly contracted; the peritoneum and large and small intestines were healthy, but the latter contained much albuminous coffee-ground material; the spleen was firm, and weighed 7½ oz.; the kidneys were enlarged and full of blood, and weighed 17½ oz. together; the shoulder-, elbow-, wrist-, hip-, knee-, and ankle-joints were healthy; the liver weighed only 33 oz., and consisted of yellow swollen bulging portions, which contrasted with depressed areas having a wrinkled appearance. The pale-yellow swollen mass on section showed the lobular arrangement of healthy hepatic structure, and two-thirds of the right lobe were composed of this; several small rounded nodules of the same kind were seen in the left lobe, but the rest of the hepatic tissue was bluish-brown in colour and homogeneous, having lost all lobular arrangement and appeared to be dotted over with white points of what seemed fibrous tissue. The dark, grumous, coffee-ground material was also present in the stomach. Microscopical examination showed the yellow part to consist of hepatic cells of normal appearance, though the protoplasm was granular or had oil globules in it. The darker part of the liver consisted of nuclei of uniform size and like leucocytes; this part also showed the highly vascular, loose-textured tissues of granulations or early fibrous tissues; there was some increase of the connective tissues around the portal canals; in many specimens an appearance as of a new formation of ducts was visible. With regard to the nature of the process, the parts of the liver where the red tissue abutted on the yellow gave the most information. Here between the rows of liver cells and between the hepatic cells themselves the cellular infiltration could be seen. There was no evidence of conversion of hepatic cells into connective-tissue corpuscles. The process appeared to be one of an acute inflammatory nature, and partook more of the characters of cirrhosis than of one of simple atrophy. He suggested that the specimen was one which should be submitted to the Morbid Growths Committee.—Mr. SHATTOCK said that the appearances resembled those of a specimen of actinomycosis, which he had recently examined, and asked whether Dr. Carrington had detected the micro-parasite of this disease in the specimen in question.—Dr. PARRY PRICE said that the specimen

resembled one which he had shown to the Society last year, in which there were bands of fibrous tissue enclosing islets of hepatic tissue; he had detected no parasite in the specimen shown by him.—Dr. BRISTOWE said that he had at first understood that the swollen yellow portion of the liver was the diseased part, but this appeared not to be the case.—Dr. CARRINGTON, in reply, did not suspect the presence of actinomycosis; he did not think that his specimens altogether resembled those of Dr. Price.

Dr. CHARLEWOOD TURNER showed a specimen of Rupture of the Thoracic Aorta. It was removed from the body of a man aged sixty-four, a labourer, who was seized with collapse of sudden onset and died from syncope the day afterwards. He had frequently suffered from faintness, dyspnœa, and palpitation. The loose stools contained some blood on the day of his admission to the hospital. At the autopsy the arch of the aorta exhibited an L-shaped rupture; the longitudinal rent was situated on the posterior aspect of the aorta. The recent transverse limb of the L-shaped rent passed round the whole circumference of the aorta. The rent led into the dissecting aneurysm, which had a wall of smooth lining membrane, and lay in the same plane as the recent separation of the coats of the aorta. The aneurysm had ruptured into the pericardial cavity, which contained a black blood-clot and some serous fluid. The aorta was atheromatous, but not in the first part; the left ventricle was hypertrophied, and its cavity nearly empty; the kidneys were granular; the cerebral arteries were atheromatous; the lungs were emphysematous. The day before the man's death it was probable that extravasation into the connective tissue of the mediastinum occurred, and the free extravasation into the pericardium probably accompanied the fatal seizure; these extravasations were due to the sudden giving way of the supporting blood-clot as the result of some sudden alteration in the arterial blood pressure. Dr. Peacock had put on record some cases of rupture of the aorta, some of which were of a T shape. In the present specimen the inner and a few layers of the middle coat were torn through in the lower part of the longitudinal rent, and the middle coat was completely rent in the upper part. A second specimen was shown of perforation of the aorta into the pericardium. The case was that of a woman thirty years of age. The arch of the aorta was extensively diseased, of dull appearance, and in many places eroded with intervening raised areas—probably in different stages of endarteritis.—Dr. NORMAN MOORE remarked on the presence of the cardiac hypertrophy associated with the condition of the kidneys, and said that in nearly every case of aneurysm of the aorta thus associated he had found that the patient was the subject of gout. In a case of hæmorrhage into the pericardium from rupture of an aortic aneurysm, where the kidneys were diseased, he had found gouty changes in almost all the joints of the body.—Dr. TURNER said that he had not examined the joints in his case.—Dr. NORMAN MOORE, in reply to a question from the President, said there were many cases of granular kidney in which no gouty changes existed in the joints.

Dr. PARRY PRICE showed specimens of Bony Deposit in the Testes and Epididymis, which were removed from the body of a man aged from fifty to sixty, who was admitted into the hospital in a comatose condition. There was cirrhosis of the liver and enlarged, slightly granular kidneys, cystitis, and two strictures of the urethra; the hard deposit in the testes and epididymis of both sides consisted of typical bone; no healthy glandular tissue could be seen in the testes or epididymis; the vas deferens was healthy. The symmetrical nature of the deposit was remarked on. The changes were probably the result of an old orchitis, following an urethritis, of which the strictures were evidence. He could find no account of any similar case. No cartilage was present in the specimen.—Mr. ALBAN DORAN asked whether there was any suspicion of the disease being of the character of a dermoid tumour. Dermoid tumours of the testes were very different from those which were found more frequently in the ovary. He did not think the specimens were related to the "dermoid class," and Dr. Parry Price agreed with him.

Dr. COLCOTT FOX showed a specimen of Primary Sarcoma of the left Suprarenal Capsule, with Thrombosis of the inferior vena cava and right auricle, taken from a child aged two years and a half. There was only a history of phthisis on the mother's side, and a possible history of syphilis in the family. The patient was the fourth child, and had always been very fat; there was a cutaneous eruption at the end of the first year, but no snuffles. When first seen, at the age of two years, she was very rickety and of bloated appearance, with a dusky hue about the cheeks, and remarkably hairy, especially about the genitals. For four months there had been enlargement of the abdomen, with a ravenous appetite and great thirst. There was a great deal of sighing. There was no œdema of the lower limbs, nor any specially enlarged subcutaneous veins. A tumour was felt in the left side of the abdomen, occupying the loin, and evidently not the spleen. The bowels were constipated; the urine was normal. Some days after first being seen she had an attack of vomiting, in which lividity and rapid breathing were observed. A similar seizure occurred later on, and the temperature was found to be 102·6°; there was a rapid feeble pulse, but no cardiac bruit could be detected; after stercoraceous vomiting the patient died. At the post-mortem examination the face and neck were swollen, the lips blue, the vulva and clitoris were much hypertrophied, the liver weighed 38 oz.; there was no clot in the portal vein; some dark grumous fluid escaped on removal of the tumour; the left kidney was healthy, but somewhat distorted in shape. The mesenteric glands were the seat of secondary deposits. There was a completely decolourised clot, filling the inferior vena cava and adherent to its walls, and reached along its whole length; it extended to and almost completely filled the right auricle, and projected through the auriculo-ventricular orifice. The uterus and ovaries were large. The tumour was about the size of a cocoanut, and had flattened the kidney; there were areas of hæmorrhage in it; it was microscopically proved to be a large-celled sarcoma. The sections were made by Mr. John Shaw. Thrombosis of the vena cava had been reported by Dr. Moxon in a case of pyæmia with abscesses in the pelvis. In the eighteenth volume of the Transactions Dr. Greenhow had placed on record the case of a girl, aged twelve years, in whom a suprarenal tumour existed. Merkel had described similar tumours. Dr. S. West and Dr. Dickinson had recorded other cases. In Dr. Dickinson's case the gipsy colour without bronzing, the enormous appetite and the vomiting, and other features closely resembled the case now recorded.—Dr. BRISTOWE said that he had seen a case of primary "cancer" of both suprarenals in a Chinese youth, and thought it was possible in the light of recent investigation that this might have been one of sarcoma.—Mr. SUTTON spoke of a specimen of a tumour replacing the right suprarenal capsule in a marmot; the liver and spleen were the seat of secondary growths. This tumour had the structure of the zona fasciculata of the suprarenal body. He had met with similar tumours in a man. He referred to a paper published by Grawitz in Virchow's *Archiv* on the subject of Supernumerary Suprarenal Capsules; tumours having the structure of the cortex of the adrenal were found beneath the capsule of the kidney, and also about the ovaries in the broad ligament. He considered that in the face of such facts we might have to establish a new variety of tumours to include those he had referred to.—Dr. DICKINSON spoke of two cases which had been under his observation. In the first case the voice was very gruff and of a bass tone; the words uttered by the precocious infant were very few, but consisted of expletives used by the lowest classes of society; the other characters had been referred to by Dr. C. Fox. The second case had been in the Hospital for Sick Children, Great Ormond-street, and was that of a female child, aged three years, who had also great development of the external genitals, which were studded with large hairs; there was an abdominal tumour having all the characters of a renal tumour, but the memory of the first case he had seen led him to diagnose tumour of the suprarenal body; the autopsy confirmed the diagnosis. In both the cases the relation of the colon to the tumour was rather different from that which usually obtained in renal tumours, for the tumour appeared to be rather above the level of the ascending colon. He thought that this clinical point might establish a distinction of diagnostic value between renal and suprarenal tumours.

Dr. NORMAN MOORE showed a specimen of Tuberculosis of the Kidneys of the Ox with Bacilli. The kidneys were much enlarged, and one completely changed into a great white mass, with hardly any remains of kidney structure except the external lobulation. One lobe of the other kidney had undergone a similar complete change, and elsewhere it showed numerous white nodules. These, as well as the completely changed kidney, showed abundant groups of bacilli, and the bacilli themselves agreed in form, method of staining, and size with the bacilli of tubercle in man. The

tuberculous part of the kidneys was nowhere broken down, but showed many zones of more or less complete calcification. The morbid change corresponded to the description of "Perlsucht," and the abundance of bacilli present confirmed the opinion that that disease was a true variety of tuberculosis, and not a lympho-sarcomatosis, as it was once believed to be.

Dr. SILCOCK showed a specimen of Congenital Sarcoma of Testes removed from a child aged eight months, who was under the care of Mr. Owen in St. Mary's Hospital. The left testicle was enlarged at the time of birth, and had gradually enlarged; it had an ovoid outline, and was not translucent; the spermatic cord was thickened; the tumour was encapsuled in the body of the testis, and sharply limited by the tunica albuginea; the tunica vaginalis and vas deferens were healthy. The tumour was a sarcoma of varying-sized cells, chiefly of spindle and oval shape. Mucoid degeneration was present in places. He said that such congenital growths were of infrequent occurrence, and no record had been found of a similar specimen. In medical literature cases of congenital "cancer" were referred to. These might possibly be sarcomata.

Mr. PARKER also showed a specimen of Congenital Sarcoma of Testes removed from a child three months old. The tumour had been noticed immediately after birth. On section it had a glistening appearance like wax. The soft matrix was composed of a large number of dilated tubules; there was much myxomatous tissue present, and also islets of cartilage. The congenital sarcomata were very rare. He had collected eighteen cases of tumour of the testicle occurring in children under ten years of age. He said that Mr. Athol Johnstone had recorded a specimen of tumour of the testicle in a child which contained a mass of bone. There had been no recurrence so far as he knew in the case from which he had taken the specimen shown. The tumours of the testicle in the child were very liable to recurrence, and the pleura was apparently a favourite seat for recurrence. He watched one case of recurrence in the pleura, and signs like those of pleuritic effusion were observed. The abdominal glands were frequently the seat of secondary deposits. In the eleventh volume of the Transactions Mr. T. Holmes had recorded a case in which recurrence took place in the lumbar glands, and a mass weighing 7 lb. was the result.

Dr. DICKINSON gave an account of an Epidemic of Renal Disease in Oxen, which had happened on the farm of a gentleman, an experimental farmer. The epidemic of "red-water" broke out in a herd of shorthorn oxen, and affected at least half the number with almost uniformly fatal result. The urine was loaded with blood, and there were casts of enormous size; turpentine was used as a remedial agent. He had examined the kidney of an ox which had survived the attack of renal disease six months. The kidney was in a typical state of interstitial nephritis. One kidney was more affected than the other; they were granular on the surface. The cause of the epidemic is unexplained. Some said it was the use of poor after rich pastures; others said it was digitalis; possibly the ingestion of "bracken" might account for the disease.

The following card specimens were shown:—Dr. Turner: (1) Ulceration of Aorta and Valves; (2) Aneurysm of Splenic Artery. Dr. Norman Moore: Cavity in Lung of an Infant. Dr. Chaffey: (1) Early Sarcoma of Testis; (2) Congenital Malformation of Pulmonary Veins; (3) Congenital Malformation of Heart. Dr. Ernest Clarke: Congenital Malformation of Heart. Dr. Hebb: (1) Two Cases of Aortitis; (2) Misplaced Kidney; (3) Tricuspid and Mitral Stenosis; (4) Cancer of the Uterus with Myomata; (5) Urethral Calculus.

HARVEIAN SOCIETY OF LONDON.

A MEETING of the above Society was held on Thursday, March 5th, Dr. T. Morton, President, in the chair.

Mr. T. W. CARMALT JONES exhibited a Single Apparatus for the Transfusion of Defibrinated Blood. The instrument consisted (1) of a receiver for the blood, in which defibrination was effected by whipping; (2) of a cannula, with movable connecting piece, for insertion into the vein of the patient; (3) of a funnel-shaped vessel, curved inferiorly like the letter L, and fitted with a perforated cap, through which pressure could be set up at the surface of the defibrinated blood by means of an indiarubber tube and hand-ball. A short piece of tubing, furnished with a spring-clip, established the connexion between the funnel-shaped reservoir and the cannula when the latter had been introduced into the vein. The various parts of the apparatus could be thoroughly cleaned, with the exception of the connecting tube, which required to be renewed after each operation.—Mr. JENNINGS said that he had listened with great interest to Mr. Carmalt Jones's able demonstration of his transfusion apparatus. For the treatment of acute anæmia (hæmorrhage being first arrested), the intravenous injection of saline fluid was sufficient to meet the exigency in the great majority of cases. Saline fluid could be safely substituted for blood up to a quantity which bore a definite ratio to the body weight (as ascertained experimentally in dogs); and it was only where this quantity had been exceeded by the hæmorrhage that transfusion of blood became indispensable. The nutritive value of blood was not to be underrated; and where transfusion was indicated for the sake of nutrition, the employment of whole blood would be better than that of defibrinated blood. This could be easily effected by means of a well-managed apparatus for the transfusion of blood and saline fluid, which Mr. Jennings exhibited to the Society (*vide* THE LANCET, Sept. 1st, 1883).

Dr. C. J. HARE read a paper entitled "Emetics: their Present Neglect in the Treatment of Disease. Is it reasonable? Is it right?" The subject of this communication was one of the numerous points referred to in a previous address on "Good Remedies out of Fashion." Although not a panacea, in certain cases emetics cured in a marvellously short time, and in others they alone appeared capable of saving life. The author passed in review the various members of this group of drugs and their doses. Speaking generally, ipecacuanha was the most useful, in doses of twenty to twenty-five grains of the powder mixed with water, or of six to eight drachms of the wine. Now and then purgation resulted instead of emesis, but persistent diarrhœa was never set up. The chief value of emetics consisted in their mechanical action upon the viscera: the stomach was not only emptied, but its innumerable follicles were cleared by pressure; the lungs were compressed and mucus forced out of the air-tubes; and the œsophagus, larynx, and fauces were swept clean. Allusion was made to cases of recurrent vomiting, commonly termed "bilious sick headaches," although more justly to be called "stomachaches in the head." The persistent vomitings were endeavours of nature to expel the slimy mucus of the gastric follicles and the morbid ferments which it contained. The desired result was often at once effected by an emetic. Many anomalous ailments, accompanied by loss of appetite, nausea, the non-enjoyment of life, ill-temper, &c., were due to a similar cause, and similarly relieved. The removal of the ropy mucus was promoted by washing out the stomach by means of warm water, which excited additional vomiting. Emetics were sometimes of signal service in severe bronchitis and in capillary bronchitis; the fear of "exhaustion" being produced by emetics was almost confined to those who never administered one. Attacks of catarrhal croup might be cut short, in children, by half a teaspoonful of antimonial wine; and in membranous croup, expulsion of the tough exudation was sometimes effected. Emetics were useful in the early stages of continued fever, of scarlatina, and of measles, and in some cases of whooping-cough. They were decidedly beneficial in the treatment of delirium tremens, and also in acute mania. By the same means the paroxysms of ague could be greatly modified, and either arrested or rendered more amenable to quinine. Drugs and diseases bear much the same mutual relation as in former ages; and as emetics were then found useful, so they would be now if fashion did not prevent their employment.—In the brief discussion which followed, Dr. DAY referred to the value of emetics in whooping-cough; and Dr. CLEVELAND insisted upon the necessity for caution, which he had learnt by experience, and pointed out that the more habitual use of purgatives in recent practice had greatly lessened the need for emetics.

MIDLAND MEDICAL SOCIETY.

AN ordinary meeting of the above Society was held on March 18th, Mr. T. H. Bartleet, F.R.C.S., in the chair.

Mr. TAYLOR showed a Fibroma of the Abdominal Parietes removed by Mr. Tait. This was considered to be a specimen of a special class of tumour, occurring in close relation to

Poupart's ligament, and into which the muscles of the abdominal wall are extensively inserted.

Mr. TAYLOR also exhibited a cast of a foot illustrating recovery after Disease of the Tarsus, in which the mid-tarsal joint had been largely involved. The internal cuneiform bone had been removed during the process of treatment, and the resulting cavity was thoroughly drained by a tube passed through the foot. After this was done the improvement was marked and rapid. The foot had been free from any discharge for nine months, and the patient was beginning to use it again.

Dr. SUCKLING showed a case in which Subcutaneous Nodules around the knee, elbow, and finger-joints were present. The patient, a girl aged nine, had had rheumatic fever six months previously; there was a well-marked double mitral bruit, the nodules seemed to be attached to the periosteum and tendons about the joints, and were painful at times.

Dr. SUCKLING also showed a case of Spinal Meningitis which had left loss of the patellar reflexes. The patient, a man aged forty, after being much exposed to cold and wet weather three months previously, had been seized with pains in the back, aggravated by movement, and hyperæsthesia of the feet which prevented him from walking. There was also loss of control over the bladder, and tenderness on percussion over the lumbar spinous processes. After free counter-irritation in the lumbar region of the spine, all the symptoms disappeared except the loss of the knee-jerks. The case was distinguished from one of locomotor ataxia by the absence of (1) characteristic lightning pains, and (2) of the eye symptoms, also by the rapid onset after exposure.

Dr. BODINGTON read a paper based on a visit to Mons. Voisin's wards at the Salpêtrière, Paris.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society took place on Feb. 12th.

Perihepatitis causing Strictures of Bile and Pancreatic Ducts, and Cystic Enlargement of Pancreas.—Dr. BANHAM exhibited a specimen showing strictures of the cystic and common bile-ducts. The pancreatic duct opened into the diseased portion of the common bile-duct, so that both pancreatic and biliary secretions had been shut off from the duodenum, with the effect of causing considerable cystic enlargement of the pancreas and dilatation of the hepatic ducts. The liver was enlarged and indurated, and there were marked evidences of old attacks of perihepatitis. Notes of the case were given. The chief symptoms had been jaundice and distressing itching of the skin, and rapid emaciation. The morbid conditions were supposed to be due to syphilis.

Charcot's Disease.—Mr. CATKIN showed a case of Charcot's Joint Disease occurring in the practice of Mr. A. Jackson at the Sheffield Infirmary. The patient, a joiner, aged thirty-seven, with a previously healthy history, applied at the infirmary some months ago with a painless swelling of the knee-joint. It was thought to be an uncommon state of things at the time, as moist sounds, &c., were to be heard at the apices of the lungs. It was at first diagnosed as hydrarthosis in a tubercular subject. Afterwards, the state of his pupils attracted attention in the out-patient room, and all the commoner symptoms of locomotor ataxia were discovered. The relaxation of the ligaments of the knees was less marked in the right knee.—Mr. ATKIN considered that this case, as well as the one brought forward by him two years ago, effectually negatived the friction traumatic theory. The joint lesion in the first case came on whilst lying in bed with a "nerve cyclone," and in this one the arthropathy preceded the ataxia.

Thoracic Aneurysm.—Dr. PORTER exhibited a case of Thoracic Aneurysm. The patient was an engineman by occupation, forty-eight years of age; there was no history of syphilis or rheumatism. An interesting circumstance in the case was that fifteen years ago the patient received a severe injury to his head by the fall of a trap-door, and a scarf-pin he wore at the time was driven into his chest for an inch and a half. For the last two or three years he had complained of pain behind the sternum, and attacks of dyspepsia and palpitation, and for two or three months of neuralgic pain down the left arm. The aneurysmal tumour was visible to the left of the sternum in the third or fourth intercostal space, and a loud, rough, double murmur audible over it. There was considerable cardiac hypertrophy and high arterial tension, but there was no inequality in the pulse of the opposite sides, or of the upper and lower limbs. There were no marked signs of nervous engorgement or other pressure symptoms. The patient had a troublesome cough, and the respiratory murmur was deficient on the left sipe, with some dulness and moist râles at the left base.

Treatment of Phthisis.—Dr. HUNT read a paper on this subject. He agreed that the disease was a modern one; and pointed out that the countries most free from it were the northern and colder regions, and he strongly recommended the selection of such countries for the cure of phthisical patients. Dr. Hunt expressed himself very sceptical on all therapeutics as remedial agents, and strongly repudiated the course of certain authorities in recommending them as cures. He had extensively employed antiseptic inhalations, but without any marked success, and was disposed to rely very little upon their potency. Iodoform was another remedy that had been tried, but the results were not such as to warrant him to recommend it in the disease. Dr. Hunt closed his paper by expressing the opinion that in the future the treatment of phthisis would come more under the domain of surgery than it had ever done in the past.

At the meeting on Feb. 26th the following specimens were shown:—

Enlarged Heads.—Mr. B. WALKER introduced two very interesting cases of enlarged heads. The first was that of a man aged twenty-eight, a hawker, with abnormal development of the left side of the frontal bone. The right side of the head measured 10¾ in., and the left 12¼ in., the enlargement being apparently confined to the frontal bone, and causing a decided projection in that region. The condition was congenital, and he had been compelled always to have hats specially fitted. His memory was stated to be remarkably good, especially as regarded objects, persons and places, figures and forms, which he never forgot. The second case was that of a girl aged twelve, and was probably hydrocephalic. As an infant she suffered a good deal in her head, and was considered to have "water upon the brain." The head measured nearly 24¼ in. in circumference. Her intelligence was not impaired; she was very useful at home, but was not so far advanced in learning as others of her age.

Aneurysm of the Aorta.—Mr. LOCKWOOD showed a specimen of Aneurysm of the Transverse Portion of the Aorta which had burst into the left lung. The specimen was from a man aged about fifty, who was admitted into the public hospital in an unconscious condition, with blood flowing from the mouth. He only lived four minutes after admission.

Genu Valgum; Wedge of Bone removed.—Mr. PYE-SMITH showed a Wedge of Bone which he had removed from the Femur of a man with severe Genu Valgum. The specimen was from the right limb, a similar one from the left having been shown at a previous meeting. The limb first operated on was well, the other was healing.

Fracture of Cervical Vertebra. — Mr. PYE-SMITH also showed part of the Spinal Column of a man aged about forty, exhibiting a Fracture of the Sixth Cervical Vertebra. The injury had been received in a fall from a dray whilst the man was intoxicated. There was paraplegia and loss of sensation below the umbilicus, except in the distribution of the ilio-inguinal and ilio-hypogastric nerves. There was good thoracic respiration and no rise of temperature. A bedsore began to form within twenty hours of the injury, and the patient died on the fifth day. At the autopsy the cord was softened and congested opposite the fracture, and there was also a softened and ecchymosed portion, with considerable effusion of blood around it, in the lower dorsal region. This latter lesion seemed to have produced the paraplegia, and the later inflammation higher up the fatal termination.

Aural Polypus.—Mr. SIMEON SNELL exhibited a large Aural Polypus. It was of the fibrous variety, and grew from the wall of the meatus. It was only of interest on account of its unusual size.

Mr. ARTHUR JACKSON read a paper entitled "Changed Aspects of Unchanged Truths: The Use and Abuse of Rest." He endeavoured to show that the great truths of physiological and mechanical rest, as laid down by John Hilton in his never-to-be-forgotten and unrivalled lecture on Rest and Pain, were being lost sight of in the theories of the present day. He urged their application in the treatment of fractures, excisions, osteotomies, and in that of wounds; and the more or less complete reform of our present mode of treatment.

WOLVERHAMPTON DISTRICT MEDICAL SOCIETY.

A MEETING of the above Society was held in the Bell Library, Wolverhampton, on April 2nd, Mr. C. G. Newnham in the chair.

Mr. VINCENT JACKSON showed a boy, aged fourteen, both of whose elbows he had excised and who had strong and useful arms; also a boy whose os calcis he had excised.

Dr. BATTERHAM showed a man whom Mr. Manby had successfully trephined for a Compound Depressed Fracture of the Skull with Perforation of the Dura Mater.

Dr. DINGLEY showed a case of Pseudo-hypertrophic Muscular Paralysis in a boy aged fifteen; also the organs of a case of purpura hæmorrhagica.

Mr. MANBY then read his paper on "Climacteric Disorder," and commenced by defining it as "a disordered state of function which tends to develop, retrograde metamorphosis coming on about the climacteric period, from forty-three to fifty, and quite distinct from the menopause in women." After graphically describing the various symptoms of this disordered condition, Mr. Manby recommended change of air and generous diet as the best treatment. At the close Dr. Totherick, Dr. Lycett, Mr. C. R. Smith, and Mr. Jackson took part in the discussiou.

Reviews and Notices of Books.

The Inhalation Treatment of Diseases of the Organs of Respiration, including Consumption. By ARTHUR HILL HASSALL, M.D. Lond. London: Longmans, Green, and Co. 1885.

THE best-known works on the treatment of disease by inhalation are those of Cohen and Oertel. The latter is practically inaccessible to the English practitioner, and the many improvements in the methods of inhalation, with the increase in knowledge of the value of this plan of treatment, which have been made since the appearance of the last edition of Cohen's valuable treatise have put it somewhat out of date. We are therefore pleased to see a recent work in which a mode of treatment now so fashionable is treated seriously, and to find that Dr. Hassall has discussed the subject so thoroughly and exhaustively. The practitioner who wishes to know the principles on which the inhalation treatment depends, the apparatus employed, and the probable value of any medicament which suggests itself as suitable for the treatment of any disease of the respiratory organs on this plan, may rely on finding the necessary information in this work. In Dr. Hassall's first and second chapters, the reader will quickly learn that inhalation as carried on in the usual routine manner is most inefficient, and that to employ it successfully the chemistry and physics underlying it must be carefully studied. He gives many experiments which show that four-fifths of the more important antiseptics, such as carbolic acid, creasote, and thymol, are recoverable after the completion of the inhalation when the ordinary oro-nasal inhalers are employed. Steam, especially when given off in a concentrated form, carries over a considerable amount of the substances enumerated, but a great loss occurs from rapid diffusion and the difficulty of confining and condensing all the vapour, whilst even with steam- and air-sprays it is doubtful if even a very small amount of the substance employed really reaches the air cells of the lungs. For a more satisfactory method of inhaling antiseptics extent of surface and a regulated temperature of from 60° to 70° F. are necessary, and the means for securing these essentials, either in a patient's own room or in a specially constructed chamber, are plainly and clearly described. The experiments in support of this method were given in THE LANCET of October 6th, 1883, and are restated by the author in his book. In reference to the treatment of consumption by antiseptic inhalations, we should have liked to have seen details of some careful experiments on the influence of various substances on the growth of the bacilli of tubercle in cultivating media, and in media as viscid as ordinary phthisical sputa. We have some information as to how small a quantity of any given drug can possibly reach the air cells; but without the further knowledge above indicated the whole process is an unscientific and empirical one, even if we allow the bacillus to be the primary factor in the causation of this disease. We have not yet the data which would justify us in describing antiseptic inhalation as a method of cure of consumption resting on a scientific basis, however valuable it may be in relieving symptoms and as an adjunct to other means of treatment in this and other diseases of the respiratory organs.

A Handbook of the Theory and Practice of Medicine. By F. T. ROBERTS, M.D. Sixth Edition. London: H. K. Lewis. 1885.

THERE is but little that calls for notice in this new edition of "Roberts' Medicine." The sixth edition appears in one volume form of suitable dimensions, and the appearance of the book as well as the clear letterpress call for expressions of satisfaction. The work gives a good representation of the present state of the theory and practice of medicine, and such a statement as this must be considered as unqualified praise when we reflect that within the compass of 1000 pages a *résumé* of the whole of medicine is comprised. In looking over the chapter on Aphasia we noticed the following sentence, the wording of which is not altogether plain. "1. There may be complete mental incapacity and loss of intellectual power, so that no ideas are originated in the mind which the individual wishes to convey, as in the case of idiots." In the preface the author thanks Dr. Beevor for assistance in revising the portion of the work that relates to diseases of the nervous system. Some students, no doubt, learn more from the somewhat rigid method of exposition which is the characteristic of the present work; and we are of opinion that where simple matters of fact have to be learnt by the student the method is perhaps better than any other that could be adopted. Where, however, a description of a pathological process has to be undertaken, we think that a system which elaborates less and which attempts a more discursive style will be found to be better suited to the exposition of the subject. The actual matter contained in the section on Diseases of the Nervous System is certainly not less than in works which are usually regarded amongst its rivals, and yet we opine that the grasp which the student acquires of this difficult subject will not be so strong as it would be were the information conveyed more in the form of continuous narrative. We confess that these are matters pretty much of individual opinion, and it is probable that the advanced student who had been well grounded in the physiology of the nervous system would perhaps acquire the facts relating to its diseases rapidly and thoroughly from Roberts' work.

The Therapeutics of the Respiratory Passages. By PROSSER JAMES, M.D. New York: Wm. Wood and Co. 1884.

IN the preface we are informed that this book is not intended as a manual for students, but mainly for those who have left the schools and entered upon the responsibilities of practice. The second chapter is the real starting-point of the work, and treats of nutrition in relation to therapeutics. This chapter gives in an almost popular form an account of the physiology of life so far as we at present know it. The theory of the conservation of energy in the vegetable and animal worlds may be perceived to underlie all the statements made in regard to nutrition. The physiological knowledge given in the chapters treating of food stuffs and digestion is pleasantly communicated.

Analeptics are agents for the promotion of healthy nutrition, and cod-liver oil receives consideration first at Dr. James's hand. Iron and phosphorus have each a chapter to themselves. Extract of malt, pepsin and pancreatin,

peptonised foods, bile, feeding by the nose or rectum, and forced feeding are all considered under the head of Aids to Digestion. A page is devoted to stimulants to digestion, which include condiments, bitters, tonics, acids, alkalies, and stomachic sedatives. The arrangement of the matter in this section appears to us to be open to criticism. Unless the context be closely kept in view the author might be understood to imply that forced feeding, and feeding by the nose or rectum, were aids to digestion. Again, it is perhaps not strictly correct to regard alkalies and bismuth as stimulants to digestion. These, no doubt, are trivial objections; but we think it would add to the orderly arrangement of the work if slight alterations in this regard were made in future editions. Amongst the best chapters in the book are those on Pneumatics and Topical Pneumatics. The term "pneumatic" in therapeutics is not in very common use; it was employed by Pereira to signify therapeutical agents which influence the functions of respiration and the formation of heat. Speaking of the work as a whole, it must be pronounced as sound and good, though in our opinion somewhat too diffuse. This is, however, partly compensated by the increased readability which it entails. Had the work been more compressed the student of it would have saved time, though possibly have lost pleasure. But the book is written for those—and we suppose there are such—to whom a little leisure is not yet unknown.

INDIAN HEALTH STATISTICS.

No. I.

THE twentieth annual report of the Sanitary Commissioner with the Government of India shows a satisfactory state of the public health during the year 1883. The average strength of the European troops for that period was 55,525, the admissions into hospital from them were in the proportion of 1336, the deaths of 10·88, the invaliding of 32·66, and the mean daily sick of 62·85 per 1000, being all lower than in the preceding year; the death-rate, indeed, is the lowest recorded in the last fourteen years. The sickness and mortality were distributed in the three Presidencies as follows:—

	Ratio per 1000 of Strength.			
Average strength.	Admitted into hospital.	Died in India.	Invalided to England.	Mean daily sick.
Bengal, 34,079	1463	11·21	30·89	65·9
Madras, 10,498	1013	10·19	32·70	58·6
Bombay, 10,948	1249	10·50	38·08	57·5

The admissions in all the three Presidencies were considerably lower than in 1882, and the deaths also show a reduction, except in Bombay, where there was a fractional increase. The invaliding from Madras and Bombay and the mean sick in Madras were higher than in the preceding year. Bengal still furnishes the highest and Madras the lowest ratios of admissions and deaths, but the reduction in the death-rate has been much greater in Bengal than in the other two Presidencies. Paroxysmal fevers cause about one-third of the admissions into hospital in Bengal and Bombay, but Madras enjoys a comparative exemption from them. In the two former the cases were in the ratio of 434 and 412 per 1000, while in Madras they amounted to 112 only. They are not the cause of much mortality. The disease which gives the highest death-rate in all the Presidencies is enteric fever. The mortality by it in 1883 was 2·52 in Bengal, 2·86 in Madras, and 1·55 in Bombay. For the whole force the admissions were 7·7 and the deaths 2·40 per 1000; consequently 31 per cent. of the cases terminated fatally. Omitting stations where only one case occurred, the proportion of deaths to cases ranged between 8 per cent. at Kurrachee and 66 per cent. at Gwalior Fortress. The influence of age upon the death-rate by enteric fever was shown by the mortality among men under twenty-five being 4·34, from twenty-five to twenty-nine being 1·50, and at thirty and upwards 0·70 per 1000. In like manner, as regards length of residence in India, the death-rate in the first and second years of service was 4·98, third to sixth years 1·55, and seventh to tenth years 0·55 per 1000 living in each period. Of 44 cases at Lucknow, 35 occurred in the Derbyshire regiment, "which arrived in India from Egypt on 24th November, 1882, and which was principally composed of very young soldiers." The months in which enteric fever prevailed most were April to September, the admissions into hospital having been 340, as against 89 in the six months October to March inclusive. "With regard to the etiology of the disease, no positive results of any value were arrived at." At Bangalore there was strong evidence of its connexion with the unsatisfactory nature of the water-supply, but in many of the other stations it could not be traced to any common cause. The European troops were remarkably free from cholera, the admissions having been only 1·4 per 1000 in Bengal, 1·8 in Madras, and 1·4 in Bombay, with the corresponding death-rates of 0·94, 0·95, and 0·82 per 1000. In Bengal the stations affected were Allahabad, Benares, Gwalior Fortress, and Chunar; in Madras, Secunderabad and Kamptee; and in Bombay, Ahmednugger and Deolali. Next in frequency to enteric fever as the cause of death in 1883, apoplexy and sunstroke rank in Bengal and Bombay and hepatitis in Madras; the ratio of the former was 1·32 and 1·10, and of the latter 1·72 per 1000 of the strength.

Venereal diseases have been a cause of much inefficiency in all three Presidencies, the admissions into hospital having been in Bengal 281, in Madras 289, and in Bombay 218 per 1000 of the strength. The cases of primary syphilis returned in each Presidency were 88, 111, and 63 per 1000, and of secondary 25, 22, and 21 per 1000.

The mortality among the women was in the ratio of 21·28, being higher than in the preceding year, but under the average. The most frequent causes of death among them were childbirth and abortion and phthisis. Among the children the death-rate was 46·88, being considerably lower than in the preceding ten years. Diarrhœa, dentition, convulsions, and anæmia were the most fatal diseases.

The average strength of the Native Army of India during the year was 114,830. The admissions into hospital amounted to 923, the deaths from all causes to 14·31, the discharges by invaliding to 28·12, and the constantly sick to 31·3 per 1000 of strength. These ratios are all much below the average; the admissions and mean sick are considerably under, but the deaths 3·43 above, those of the European troops during the same period. The sickness and mortality in the three Presidencies respectively were as follows:—

	Ratio per 1000 of Strength.		
	Admitted.	Died.	Constantly sick.
Bengal	985	13·98	32·0
Madras	737	12·51	27·5
Bombay	994	14·96	34·7

This table shows the Bombay Presidency to have been the most unfavourable to the health of the native troops. Paroxysmal fevers were the most prevalent diseases in all the Presidencies; but, as was the case with the European troops, gave rise to a considerably lower proportion of admissions in Madras than in the other two Presidencies. The cases of intermittent fever were 398 in Bengal, 389 in Bombay, and 271 in Madras per 1000 of strength. The Native troops continue to show a marked exemption from enteric fever, only eighteen cases and five deaths having been returned from the whole army. Cholera did not prevail to any extent in Bengal or Bombay, but in Madras the admissions amounted to 6·2 and the deaths to 2·92 per 1000 of strength. Its prevalence was confined to Secunderabad, Kamptee and Raipur, Vellore and Trichinopoly, and among troops on the march, and two fatal cases occurred at Toungoo in Burmah. Twenty-five cases and fifteen deaths occurred in the Hyderabad contingent, and of these ten, with three deaths, were in the 2nd infantry at Ellichpur. The most fatal diseases among the Native troops were those of the respiratory system, the deaths by which amounted to 3·20 in Bengal, 4·62 in Bombay, and 1·66 in Madras per 1000 of strength. The prevalence of venereal diseases in the Native army offers a very marked contrast to that in the European force, the admissions having been only 31·6 per 1000, as against 270·3. The usual summary of the sanitary sheets of the Native Corps is given. They indicate a considerable amount of overcrowding and of insufficient ventilation, and there seems at many of the stations abundant room for improvement of the drainage and of the general sanitary arrangements.

THE LANCET.

LONDON: SATURDAY, APRIL 11, 1885.

THOUGH we do not always agree with Sir WILLIAM JENNER, there is no doubt that the College of Physicians is to be congratulated on having again re-elected him to the Presidency. There are doubtless other Fellows of the College entitled to fill the chair, and qualified to do so with advantage to the College, but it is no disparagement to them to say that they can wait, and that such a Corporation as the College does well, when it finds a representative physician, to make much of him, and to refuse to let him go. The address which Sir WILLIAM delivered touched upon subjects of much interest to the profession, and we propose to dwell on one or two of the principal of these topics. Referring to the high fees charged for the double diploma of the conjoint examination, Sir WILLIAM defended them as unavoidable till the scheme was well established. We cannot see this, and we venture to think that the good establishment of the scheme would be promoted by making the fees more equal to those for similar examinations elsewhere, and more proportionate to the nature of the merely qualifying diploma for which they are paid. On the next topic we are sorry to be obliged to agree with Sir WILLIAM JENNER—in attributing the withdrawal of the Medical Bill of last year to the determined opposition of the Scotch universities. Sir WILLIAM JENNER'S position as the President of the College of Physicians and an ex-Royal Commissioner gives great weight to this statement of the responsibility of the Scotch Universities, as to which indeed there can be no doubt, after the amendment of Sir LYON PLAYFAIR and the obvious effect of his fallacies and platitudes on the resolution of those responsible for the Bill. The action of the Scotch Universities was most unfortunate for themselves. It was inconsistent, as they had in the previous year given the Bill a public-spirited support, as calculated to raise the character and dignity of our medical examining system. Secondly, it gave occasion to the enemy to decry and to disparage the system of graduation in the Scotch universities, and to represent it as no better than that of the English corporations. Thirdly, it gave great impetus to the determination of English teachers to have an easy method of graduation for the benefit of London students and London schools. This determination found expression in Sir WILLIAM JENNER'S address. Our readers know how heartily we desiderate legislation that will put the medical schools of London into such relations with a living teaching university as to facilitate medical graduation for London students. But we fear that Sir WILLIAM JENNER'S views on this subject are open to grave objection. The President of the College sees, of course, what is only too patent, that the London students are lured to Edinburgh and other of the Scotch universities by their degree-granting powers. The regulations of the universities require residence for two years at least. The London University—a mere examining board—hitherto has had no pity for the best medical teachers thus deprived of their best students. Like too many of the alumni of this university, Sir WILLIAM seems hopeless of its having wisdom enough to submit to such changes as would be for the good of medical education in the largest city in the world. He is probably rather hopeless too, as well he may be, of the English Parliament within any reasonable period having either inclination or time to compel the University of London to come down from the clouds and make it what it was intended to be. Under these discouraging circumstances, Sir WILLIAM makes a suggestion that the two Colleges, in their conjoint form, might undertake an inquiry as to the best means of obtaining the favour to grant degrees. From the tenour of his language we should gather that he believed that the Colleges themselves might aspire to this high function and become degree-granting bodies. This seems to us to be an entirely inadequate suggestion. It is not in the nature of things that professional corporations should grant Degrees; and it would be a serious degradation of degrees and of their value if everyone passing the lowest qualifying examinations of the corporations were to become entitled to the highest and most coveted medical title. This would be levelling up with a vengeance. It would be to deal a deadly blow at the value of Degrees altogether, and to make distinction consist in not having them, or in having them and not using them. We cannot believe that such a step will ultimately have the approval of Sir WILLIAM JENNER or of the College of Physicians, which has always held high the distinction of graduation, and recognised that the conferring of degrees and of the titles attaching to them was the work of universities.

There are two questions which we should like Sir WILLIAM JENNER to consider, or the Conjoint Board to whom he would depute the inquiry concerning degrees for London students. First, is it to be believed that a degree from two London corporations would be considered equivalent in public value to those of ancient and well-ordered universities where all the Faculties exist, and lend lustre and *esprit de corps* to the whole body of graduates? Secondly, if the Corporations of London claim and receive the power to grant degrees, what is to hinder the Corporations of Edinburgh from doing the same? Obviously nothing. After this would come the deluge, and the whole system of graduation would be discredited. Men would cease to strive for that which had ceased to be an honour. We are not fearful of such a calamity, for whatever the faults of the existing universities, they have not yet so utterly lost influence in the State as not to be able to prevent such a blow at one of their chief functions. There is yet one more, but sufficient, objection to such a scheme as Sir WILLIAM JENNER seems to contemplate—namely, that it would give a false appearance of satisfying the deep and wide demand expressed for a true, complete, teaching University for London, in the ordinary and comprehensive sense of that word.

THE Government Bill to amend the Laws relating to Lunatics has been printed, and although in many respects its provisions will need to be modified in passing through Committee, it is certainly a measure which must be accepted as embodying considerable and salutary reforms. The salient defects happily admit of amendment by very simple changes.

The most urgent of these is a shortening of the period during which the protection extended to persons placed in an asylum under "urgency certificates" is to be withheld. Practically there is little fault to find with the safeguards provided for the protection of ordinary cases which, after this Act comes into operation, will be submitted to the supervision of a County Court judge, a stipendiary magistrate, or a justice of the peace; instead of being rushed secretly into an asylum without any sort of check on the *bona fides* of the person making the "order." Henceforth orders will, in the regular way, be made by magistrates only. There is, however, a dangerous loophole left for wrong-doing by the adoption of the method of incarceration by "urgency certificates." In itself, this method, which has been borrowed from the Scotch system, is admirable, and will fulfil many useful purposes; but it would manifestly be destructive of the principle of the measure to permit a weak-minded or eccentric person to be put away in an asylum with a single medical certificate, and left in the midst of lunatics for seven days before a petition were presented to a magistrate. Yet this is the effect of the Bill as printed! Again, a report is to be made to the Commissioners a *month* after the admission of a patient to an asylum. Why a month? If a month, and then so much longer as may suit the convenience of the Commissioners in Lunacy, are allowed to elapse before the lunatic is visited, obviously great harm may be done. The *idea* of the Bill is to provide that in *all* cases of admission to an asylum there shall be a special visit to the new inmate within a reasonable time after his reception. This is an excellent measure, but it is absolutely necessary that the visit should be paid much more promptly than at the end of a month, *plus* so much longer time as may be implied by "as soon as conveniently may be." As the Bill is drawn, it may very well happen that two months or more will elapse before the visit which is to act as a safeguard is paid, and long before that time the new inmate may be hopelessly insane. In the case of a patient admitted on an "urgency certificate," it is, as we have said, imperative that the magistrate should interfere in less than seven days. A very little reflection must suffice to make it plain that the danger of wrong-doing will be rather increased than diminished under the proposed Act, unless the powers given under the urgency clause are very carefully guarded.

Speaking generally, the aims of the Bill are good, and not only well directed, but thoughtfully and carefully carried out. Too much, however, is left to the Commissioners, who are assumed to be immaculate, whereas it should be borne in mind by the Legislature that the need for reform has to a large extent arisen out of the careless and perfunctory manner in which the Commissioners have hitherto discharged their duties. If the Commission had not been largely composed of men trained in the evil ways of the asylum-system, and very little in earnest for the interests of the insane, the laws already in existence would have sufficed for the protection of both the sane and the insane. Laws are made for those who either themselves do amiss, or by their error or apathy allow others to offend against the welfare of society. It is indispensable that the most stringent precautions should be now taken to keep the Commissioners up to their work, and to compel them to discharge the obligations of their office in no perfunctory fashion. Let those who doubt this only reflect on the way in which the provision for the scrutiny of certificates by the Commissioners has been carried out. As a matter of fact, it has been the boast of the Chairman of the Commission that extremely few certificates have been found to be defective. What does this mean? Simply and plainly that the Commissioners have not troubled themselves to look beneath the merest surface technicalities. For example, if in filling in a form the certifying person chanced to omit a statement in some blank space of the vocation of the alleged lunatic, he would be called to order; but if he filled another blank space with the veriest rubbish in the way of evidences of insanity, the Commissioners cared nothing for that palpable fact. Unless something be done to make these gentlemen understand that they are to do more than mere clerks' work, the provisions of the Act will fall flat. Let anyone who knows the working of the Commissioners' office at present ask himself what is likely to be the practical result of a provision such as this: "In the case of a private patient in an asylum, the Commissioners, after receiving the report [that is, the report to be sent to them by the medical officer of an asylum at the expiration of one calendar month after the reception of a private patient], shall either make arrangements for a visit being paid, *as soon as conveniently may be*, to the patient therein named by one or more of the Commissioners, or," &c. Beyond question, in as many cases as possible the Commissioners will content themselves by referring the matter to the committee of visitors of the asylum, as the Act allows, and for the rest, "as soon as conveniently may be" will mean anything from a month to three months. Probably it will amount to this, that at the next routine official visit to the asylum the Commissioners who chance to go will be charged to inquire for the patient named in the report, and his or her name will perhaps have two ticks on the list instead of one. If any good is to be done by the passing of this Bill, failure through official neglect must be guarded against at every point. Nothing can safely be left to the Commissioners in Lunacy, and unfortunately much has been left to them, with the gravest peril of reducing the Act to the level of a new incumbrance of the statute book. The provisions throughout are far too permissory in their character. They should order where they now simply allow. This is especially necessary in all that relates to the main purpose—namely, the protection of the alleged insane.

The effect of the measure as regards the gradual superceding of the private-asylum system is, we think, likely to be satisfactory. The Secretary of State can enforce the provision of sufficient accommodation for both pauper and non-pauper cases; and the interest of local financiers will be to receive private patients into public asylums because the profits made in this way can be applied to the relief of the rates by defraying other costs of the asylum. This appeal to the commercial instinct may doubtless be trusted to produce sound fruit. It is much to be regretted that the care of the "sane or insane" cannot be placed on an equally practical footing with respect to the discrimination between suitable or unsuitable cases. Unfortunately, when the committees of public asylums become *de facto* themselves private asylum keepers, making a profit out of every

paying case they can accommodate, there will be less rather than greater reason to trust to the security their disinterested vigilance is supposed to supply, and to which the new measure attaches very considerable importance. On the whole, as we have said, the Bill is a good one, but it will need to be amended in many points to make it consistent with itself.

IN another column will be found some remarks by Dr. WILKS upon the efficacy of arsenic as a remedy for certain obscure cases of anæmia and atrophy. Few are better qualified than Dr. WILKS to advocate a remedy for such conditions, which have been often made the theme of his suggestive essays; nor do we think his apology is needed for bringing the subject under the notice of the profession. For no one will accuse Dr. WILKS of over-estimating the value of any drug; he is, if he will allow us to say so, far too much imbued with scientific caution to lavish undeserved credit on any pharmacopœial preparation. It is this fact which makes his testimony of so much value, confirming so strikingly the opinion that is now tolerably widely established as to the importance of arsenic in therapeutics. Perhaps the most striking examples of its efficacy are in those cases of idiopathic anæmia in adults which, owing to their mostly fatal progressive course, were, as Dr. WILKS somewhat cynically reminds us styled "pernicious;" cases of blood-impoverishment, which appear to depend upon some defect in the process of blood-formation, but the precise etiology of which still remains shrouded in obscurity. The testimony of Dr. WILKS on this point is borne out by the experience of many physicians; amongst the most recent being Dr. WARFINGE of Stockholm, who reported several cases of remarkably rapid arrest of the downward progress of the disease, and even of recovery, under the use of arsenic. All such cases should, however, be subjected to prolonged supervision, as it is notorious that relapses are prone to occur. The same remedy has been also successfully employed in an even more definite cachexia—viz., Hodgkin's disease—where the internal administration of arsenic has been supplemented by its injection into the hyperplastic lymphatic glands with, according to WINIWARTER, astonishing result.

The list of conditions, exclusive of cutaneous and nerve affections, in which arsenic has been found empirically useful, is a very long one, and to it must be added such cases of general atrophy or marasmus, to which Dr. WILKS now draws attention. But, as is so often the case, the fact of a remedy being useful is admitted and recognised long before any satisfactory rational explanation of its mode of action is arrived at. This is pre-eminently the case with arsenic; for although experimentation has shown that it has most powerful effects upon tissue metabolism, there is a lack of harmony in results that prevents an exact conclusion as to the precise direction in which that change occurs. Thus, it has been asserted by some to promote oxidation, by others to lessen it; by some to act destructively upon the blood-globules, by others to reinforce them; some find an increased excretion of urea under its use, others a diminution of this product. One view of its mode of action is that its compounds readily take up and part with the oxygen they contain when in contact with protoplasmic molecules, arsenious acid being oxidised in the blood, and the resulting arsenic acid being reduced by such contact; in other words, that it acts vicariously for hæmoglobin. Hence its value in conditions where that essential agent to metabolic processes is diminished or in abeyance.

Dr. WILKS declines to speculate upon the *modus operandi* of the drug, and we will not rush in where so skilled an observer fears to tread, for the ground is so uncertain, and knowledge of the intimate processes of nutrition in health as yet so incomplete, that it is not possible to advance more than theoretical explanations of the reason of its efficacy. We must be content with proclaiming the fact that in arsenic the practitioner possesses one of the most valuable of drugs, of especial value in cases of profound nutritional disorder, which seem to depend, not upon the derangement of any single organ, or upon the extension of such morbid processes as tubercle or cancer, that sap the vitality of the organism, but upon some as yet hidden and mysterious disturbance of the normal dynamics of nutrition, in which both blood and tissue seem everywhere to be at fault. Until physiological and pathological research shall have elucidated more clearly these intimate processes, it is idle to speculate on the action upon them of therapeutic agents.

THE *Morning Post* has discovered a new *opprobrium medicinæ*. There is something fine in the dogmatism with which our contemporary settles that Lord CAIRNS a week before his death was a strong healthy man, and that the responsibility for his death from a "mere chill" lies at the door of "medical science." The sentence in which the conviction of the writer is expressed must not be "let die."

"Now we have no hesitation in saying that, notwithstanding the boasted progress of late years in medical science, it is simply an *opprobrium medicinæ* when a man full of health and vigour is sent to the grave through the operation of a disease which every physician would admit is curable if taken in time and properly treated."

This absence of hesitation is a quality in public writers which is very much admired by a large class of readers, and we do not like to say a word that would qualify their enjoyment of the deliverance of our contemporary, that such deaths as Lord CAIRNS' are a disgrace to medicine, and due entirely to the abandonment of the good old practice of "drawing blood in large quantities from the patient." Unfortunately our contemporary's authority, though great in questions of fashion, does not extend to the fashions of medical practice, and we find his argument vulnerable at every point. So far from knowing so much more than others, and being entitled to rate the degenerate representatives of medicine, he betrays a striking ignorance of what all the world but he himself knew well. He assumes that Lord CAIRNS was a man of strong health and vigour, whereas it is notorious that he was not so, and his residence at Bournemouth was determined by the very delicacy of his health. He further assumes that the deceased nobleman was perfectly well up to the time of a certain shower to which he was exposed, forgetting that, like the rest of his fellow-countrymen, he had been continuously exposed to two months of biting east wind, without the power of resistance that many have. Then our contemporary holds "medical science" responsible for Lord CAIRNS' death, whereas it is notorious that the noble and good earl, with all his acumen, did not appreciate what the

medical profession would understand by medical science, but preferred to be treated by the representatives of a medical system which is ignored by every University of Europe and by scientific men generally, and the chief representatives of which in England have fundamentally changed their ground. But where our contemporary has gone farthest wrong is in supposing that there is an alarming increase in the frequency of such deaths as that of Lord CAIRNS as compared with the palmy days of bloodletting. No mistake could be greater. The mortality of such cases has been immensely reduced by improvements in modern treatment, and especially by the leaving in the veins of the patient the large quantities of blood which used to be "drawn," as our new censor says. One physician alone, the late Dr. J. HUGHES BENNETT, has recorded 105 cases of *uncomplicated* inflammation of the lungs *without one death*, though many of the cases were severe, involving the whole of one lung in fifteen and both portions of lungs in twenty-six cases. His system of treatment, now generally followed, is described by himself as "treatment by restoratives, directed to further the natural progress of the disease and supporting the vital strength." He entirely avoided "drawing" large quantities of blood, under which the mortality was certainly infinitely greater. We cannot answer for the treatment pursued in Lord CAIRNS' case. It is quite possible, in the dilapidated and demoralised state of homœopathy, that it did not differ from that practised now by most sensible physicians. The fatal result may have been due to the occurrence of a sharp pulmonary congestion or a pneumonia in a constitution by no means vigorous or healthy, and worn by the labours of an anxious profession and position. But one thing we will venture to say without hesitation, that the omission of phlebotomy was not a subject for censure, and that our contemporary will have to find other cases than that of Lord CAIRNS on which to revive a practice so questionable as the "fashion" over the disappearance of which he seems to sigh, and which, like many other fashions, is generally more honoured in the breach than in the observance.

THE lecture on the Sanitary Condition of our Homeless and Nomadic Populations, delivered by Dr. RICHARDSON on Saturday before the Association of Sanitary Inspectors, has struck a chord which has caught the attention of the people in a very remarkable way. It is one of the often-expressed sayings of the author of the lecture that many of his efforts which have gained most public favour have been those which have cost him least trouble and the smallest amount of preparation. The lecture opened with an intimation that the services of the sanitary inspectors might be extended with good purpose and effect to the inspection, under skilled direction, of the condition of the people who live without any fixed home. The people thus named were then divided into three classes. The first, the vagrant class, who have no home of any kind, who sleep anywhere, and get food anyhow. The second, the itinerant trade and showman class, who wander about the country in vans, using the van as the living and sleeping house, as well as the storehouse. The third, the pure nomadic class, who still live altogether under canvas—tent-dwellers proper, or gipsies. The conditions of health of these three classes were then compared and contrasted *inter se*, and, by inference, with the members of the ordinary community. To the vagrants a life of a truly unhappy and worthless kind was accorded, but it was indicated that with all their misery they and theirs were less subjected to the decimating zymotic diseases than the members of the industrious populations aggregated in large cities and towns. It was further pointed out as a singular fact that these vagrants wandering to and fro amongst the people, wearing the cast-off and often infected clothing of the people, and occupying common lodging-houses in which the most simple hygienic rules prevail, rarely carry about with them any of the contagious diseases, and rarely suffer from them. The same rule was to a certain extent true in respect to the people who travel and live in the vans, but these are much more subjected to other diseases, induced even in the midst of nature, "under the canopy itself," when they begin to shut themselves and their families up "in a travelling experimental room." They then become anæmic and scrofulous, and are affected with consumption of the lungs from a rude and unscientific, though practical, synthesis of that formidable destroyer. As to the true nomads or gipsies who continue still to live in tents, their fate is indeed singular, in so far as the lecturer's observation extended to them, observation which seems to have won the special attention of hearers and readers. Dr. RICHARDSON said that in his early professional life, when he was associated in practice with the late well-known Dr. ROBERT WILLIS of Barnes, he had under his care for some months, on Barnes-common, a gipsy lad living in a tent, who had sustained an injury to the spine, and that during this long attendance he had gathered a number of facts relative to the gipsy life, and had learned a little of the language of this singular Indian trail, some words and sentences of which he still remembered and explained. From this and later sources of information he came to the conclusion that the gipsies, perhaps comparatively short-lived—although there were exceptions to this rule,—are remarkably free, so long as they remain in the tent, from the spreading diseases of the community at large. They seemed in this primitive condition to know nothing of small-pox, though little protected by vaccination, and he had never met with one of them pitted with small-pox. In 1850-51 the gipsies on Barnes-common were surrounded with cases of scarlet fever in the neighbouring places, but they all escaped, although they took no precautions, and in fact were absolutely ignorant or indifferent about the matter. More curious still was the statement of the lecturer that he had failed to find a gipsy man, woman, or child in the pure nomadic state who showed evidence of syphilis, either in its primary, secondary, or tertiary stages, and he referred to the perfect condition of their teeth as a corroboration of the truth of this noteworthy observation. When the nomadic gipsy changed his mode of life, when he settled in cities and towns, and so came "under the influences of a higher and more cultivated civilisation," then, doing at Rome as Rome does, he gets what Rome gets. But in his primitive state he seems to escape this, the most corrupting scourge of the human family in its more advanced social life. Altogether, the lessons derivable from the lecture were that poverty of itself, unless pushed to absolute famine, had nothing to do

with the occurrence of the zymotic diseases; that fresh air is the one mighty disinfectant; and that luxury and density of population are the two bad spirits that conjure up the great physical evils of humanity, and necessitate the existence of an army of protectors, of which our profession is the body and soul, against those evils. That the views and suggestions offered by Dr. RICHARDSON in his lecture are to be taken with all proper qualifying experience, to be sought out in the future, is what he himself anxiously asked for, and which we therefore may fairly urge. He had, he said, merely afforded a nucleus for further information, and he enlisted the services of the sanitary inspectors of the kingdom to report to him on a series of questions which he has drawn up for their and his own future guidance. We feel sure that the members of the profession will be glad to take part in a labour which, commenced by one of their own body, deserves to be supported generally, as affecting importantly the health and education of the nation at large.

Annotations.

"Ne quid nimis."

PROFESSOR MACLEAN OF NETLEY.

A FAREWELL dinner was given at the Medical Staff Mess, Netley, on the 31st ult., to Professor Maclean, C.B., whose official connexion with the Army Medical School terminated on that day. About fifty medical officers and guests were present at the entertainment. The Director-General of the Army Medical Department, who came from London to attend the dinner, proposed the toast of the evening in a speech characterised by much feeling and ability, and in the course of it gave a review of the long and valuable services of Dr. Maclean, not only at the Army Medical School, but also while serving under the Indian Government in the Presidency of Madras, where the accidents of service had caused them to be frequently associated. Professor Maclean, who replied with much emotion, said it was a source of the greatest satisfaction to him that, now he was quitting active employment in the Army Medical Service, he could feel he was leaving the department in a more efficient state of organisation for carrying out the important duties with which it is charged, in time of peace as well as in time of war, than it had ever had in former years; and in taking leave of his colleagues and brother officers he particularly congratulated them that the professorship he had held was now passing into the hands of an officer who had had such varied and extensive experience in tropical disease, and who had won for himself so distinguished a name in India, as Dr. David Boyes Smith.

THE PORT OF LONDON.

ACCORDING to the report by Dr. Collingridge for the second half of 1884, 12,111 visits of inspection were made to vessels within the limits of the port sanitary district of London. Attention is drawn in the report to the dangerous practice of bringing home in ships the clothing and effects of persons who have died of infectious diseases abroad; and during 1884 the clothing of cholera victims was included amongst these articles. Unless there is the most distinct evidence that such articles cannot have been exposed to infection, the practice of the port officers is to burn them and to recoup the owners. The cholera epidemic in Europe is entered into in some detail; and it is shown that considerable arrangements had been made for dealing with the disease had it made its way into the port. In connexion with the prevalence of infectious diseases, Dr. Collingridge calls attention to a curious anomaly in port sanitary administration. At the present time all bills of health are signed by the Customs officers, who have no proper means of judging of the real health of ports, and who are hence practically limited to the ordinary channels of information. Since infectious cases within ports are reported to the officers of health, it is obvious that they, and not the Customs officers, should sign the documents in question. The present arrangement is, of course, a remnant of a system which was antecedent to the universal appointment of officers of health in ports, but the time is approaching when it should cease. The new hospital on the banks of the Thames below Gravesend has been of great service in the isolation and treatment of cases of infectious diseases, and with a view of adding to its efficiency a covered boat fitted with a cabin for the comfortable conveyance of two persons in a recumbent position has been provided for the purpose of removing patients from ships. The polluted state of the Thames is once more adverted to. Last August the river was more foul than it had ever been before the cleansing of the upper reaches having been carried out at the expense of the lower, and the result was that attacks of vomiting and diarrhœa occurred in passengers coming up the river in consequence of the effluvia. The so-called "deodorisation" carried out by the Metropolitan Board of Works is stated to have been quite useless beyond causing a slight smell of chlorine in the neighbourhood of the outfalls. The cool weather and the rain which followed at the end of August alone led to a temporary abatement of this gigantic metropolitan nuisance. It is to be hoped that measures will before long be undertaken to remedy a state of affairs which, resulting as it does from the discharge of sewage in its crude state into the river, has been declared by the Royal Commission to be "neither necessary nor justifiable."

A NEW ANTISEPTIC.

SOME articles have appeared in recent numbers of the *Boletin Farmacéutico* of Barcelona, calling attention to a drug which seems to be well known in Spain, but which, not having been in the writer's opinion prescribed with due regard to its physiological properties, has disappointed many, and so has fallen into undeserved disrepute. The drug referred to is helenina, the active principle of Inula helenium (elecampane). It was formerly used for itch and herpes, also as an anthelmintic. It has now been found to have powerful antiseptic properties. Dr. Korab found that fifty centigrammes were sufficient to entirely arrest putrefaction in five litres of urine—i.e., 1 in 10,000 parts. The writer of the articles has also made some experiments. A slice of veal sprinkled with a solution of 25 centigrammes of helenina in 2 grammes of alcohol, and kept at a temperature of 28° C., remained perfectly sweet for ten days, by which time it was completely dried up. An egg beaten up with 300 grammes of water, to which was added 30 centigrammes (about five grains) of helenina dissolved in two grammes of alcohol, remained unchanged at the temperature of 28° C. for six days. Another egg similarly beaten up without the drug, and kept at the temperature mentioned, rapidly decomposed, and in twenty hours emitted a strong odour of sulphide of hydrogen; to this a solution of 50 centigrammes of helenina was added, and in a few minutes the offensive odour had disappeared, and the mixture underwent no further change. Similar experiments with urine, meat, and beaten-up eggs were made with carbolic acid, boracic acid, and salicylic acid, instead of helenina; but much larger proportions of these substances were required to prevent putrefaction, and none of them were capable of arresting commencing putrefaction

of the egg, as helenina had done. Korab found that a few drops of a solution of helenina immediately killed the organisms in ordinary infusions, and also in cultivations of the tubercle bacillus. While the writer was working with helenina in his laboratory, he noticed that the bad odours usually present in the vicinity were replaced by the aromatic smell of the drug, due to the washings thrown away. He also noticed that insects, which were commonly very numerous, were at that time absent; even the mosquitoes were kept away from the whole house during the months in which they specially abound. The drug has proved most valuable in surgery as an antiseptic when carbolic acid and other agents had failed. It has been successfully given internally in malarial fevers, tubercular, infantile, and catarrhal diarrhœa; and it is expected to prove an excellent substitute for carbolic acid in the Listerian system of aseptic surgery. The dose is about a third of a grain in pill or mucilage, and the price about a penny a grain.

THE FAVERSHAM JOINT HOSPITAL BOARD.

COMBINATION of sanitary authorities for the purpose of providing infectious diseases hospitals has so many advantages that the system has been largely favoured by the Local Government Board. The scheme involves but a comparatively small increase of cost over a hospital provided by a single authority, for one site, one boundary wall, one set of buildings for ambulance, laundry, disinfecting, and mortuary purposes suffice for two authorities, just as it does for one only; and even as regards the ward-pavilions, only some increase in the number of beds, and not of the buildings, is, as a rule, needed. Some time since, on the application of the urban and rural authorities of Faversham, and after public inquiry at which all parties seemed unanimous, the Local Government Board issued a provisional order forming the two authorities into a joint hospital board. From that moment, however, dissensions appear to have sprung up; disputes occurred as to the site and the character of the buildings, and at last the joint board suspended its meetings, having in the first instance applied to the central authority to be dissolved. But the board having been formed with the approval of Parliament for a definite purpose, the Local Government Board decline to sanction the dissolution except on the definite understanding that each authority will singly perform its duty in the matter of providing means of isolation. No such guarantee appears to be forthcoming, and the whole matter is at a deadlock. This is to be regretted. Both authorities have a considerable population among the labouring classes, who, when infectious disease appears in their homes, have no proper means of accommodation for the sick, and are utterly without such means as would suffice to stay the spread of infection. The elections which are about to take place as to local affairs may perhaps set the matter again on a proper footing, and thus the two authorities may be spared from acting without proper judgment in regard to a step which is of considerable importance to the health of their respective districts.

TRANSFUSION OF BLOOD.

THE public mind has been much astonished and bewildered during the past few weeks by the reports, through the general press, of certain experiments on transfusion of blood said to have been carried out at Denver, Colorado. The popular mind has been astonished and bewildered many times before now on the subject of transfusing restoratives into the circulation of men and animals. The operation starts, indeed, in mystery. Æson, the father of Jason of the Golden Fleece, becoming infirm, Medea, after drawing the blood from his veins, refills them with a potent fluid, and the old man, so runs the fable, rejuvenates. Libavius of Halle, in the early part of the seventeenth century, improves on this fable by suggesting the actual transfusion of blood. Christopher Wren, in the eighteenth century, gives the idea more distinct form; and Richard Lower, Edmund King, and Denis actually bring it into practice, with such effect that the world, startled by the first results and filled with admiring wonder, soon turns round, in disappointment at failure, and lets the Pope prohibit the operation in all parts where his mandate was law. Over and over again the wonder has, nevertheless, revived. Early in this century, Professor Harwood of Cambridge revivified a pointer that had been bled, as it seemed, to death by transfusing into it the blood from a sheep. Later on in the century Dr. Blundell made some remarkable experiments precisely similar in character, and now we have the same retold in a new dress, either by repetition of mere narrative or by repetition of experiment—which it is difficult as yet to say. Of the report going the round of the press it is quite impossible, at present, to speak with any certainty. The account may be nothing more than a piece of clever writing based on an imperfect knowledge of previous researches. It may be the account of some experiments similar to those we have described, but reported with more of enthusiasm than accuracy. We cannot tell. All we can say is that the absence of technical mode of description, some errors of detail, and the absence of reference to all previous research on the subject, together with the notice of many proceedings which according to our present knowledge would destroy the value of transfusion as a means of restoring suspended life, make us most cautious in accepting any part of the statement until it is corroborated by other and more trustworthy evidence.

FRUIT AS AN ARTICLE OF DAILY DIET.

ONE of the most salutary tendencies of domestic management in our day is that which aims at assigning to fruit a favoured place in our ordinary diet. The nutrient value of such food, in virtue of its component starchy and saccharine materials, is generally admitted; and while these substances cannot be said to equal in accumulated force the more solid ingredients of meat and animal fat, they are similarly useful in their own degree, and have, moreover, the advantage of greater digestibility. Their conversion within the tissues is also attended with less friction and pressure on the constructive machinery. The locally stimulant action of many subacid fruits on the mucous membrane deserves mention. Its control of a too active peptic secretion, and its influence of attraction exercised upon the alkaline and aperient intestinal juice, are points of more than superficial importance. To this action further effects, which aid the maintenance of a pure and vigorous circulation, are indirectly due. Thus it follows, on the simplest principles of physiology, that other essential organs, such as the skin and kidneys, are relieved by the transference of part of their excretory function to the bowel, and act with greater ease, the general vascular system is lightened by this regulating drain, and its faculty of absorbing the waste products of food and work is encouraged in proportion. Almost all persons in fairly normal health may partake of sound and ripe fruit in greater or less amount. Except in certain cases, indeed, there is practically no exact limit to its consumption under these circumstances. Among such exceptions may be noted the gouty and rheumatic diatheses. A tendency to diarrhœa or a dysenteric history obviously forbids the free or frequent use of fruit. Saccharine diabetes, or nervous conditions in which it is apt to appear, are similarly antagonistic—at all events where any but the non-amyloid fruits, such as nuts, are considered. Dyspeptic stomachs, on the other hand, are usually benefited

by a moderate allowance of this light and stimulating fare. It must be remembered, moreover, that every fruit is not equally wholesome, let the digestion be as powerful as it may. Nuts, for example, consisting as they do, for the most part, of condensed albuminoid and fatty matters, cannot compare in acceptance, either by the palate or the stomach, with other more succulent kinds, even though they contain in the same bulk a far greater amount of nutriment. A little of such fruit is enough for digestion, and that little is best cooked. Nevertheless, if we take fruit as a whole, ripe and sound of course, and consider its variety, its lightness and nourishing properties, whether eaten alone or with other food, and its cheap abundance, we cannot hesitate to add our voice in support of its just claims on public attention. In former articles we have shown why vegetable produce of all kinds should enter largely into the food of children. Well-chosen fruits are consequently for them as safe and beneficial as agreeable.

THE GENESIS OF CANCER.

A MARKED increase in the death-rate from cancer during the latter part of the present century has for some years occupied the minds of several well-known pathologists in endeavours to reveal its cause. There is a pretty general agreement with regard to this disease that it is prone to arise out of prior morbid states which do not appear to be directly or necessarily related to it. It is evolved as a successor to innocent tumours, or in the track of an old inflammatory lesion. It rises apparently *de novo* out of mere senility or exhaustion of tissue, its permanently rudimentary type representing the best efforts of wearied nature to make good the daily wear of more perfect structures. On the other hand, cases occur in which, without impairment in any visible degree of vital power, the energy of some local irritant appears to master so completely the normal process of growth as to maintain its elements in the exuberant imperfection of the malignant tumour. Manifestly the same irritant acting on weak tissues is still more likely to work out its pernicious consequences. If we admit, therefore, as we consistently may, that tissue exhaustion, the result of toil, anxiety, or privation, and whether inherited or directly induced, affords a sufficient basis for the development of cancer, we need not look far into the history of our laborious age to find an explanation of a rise in its death-rate which at first may seem to be anomalous.

WELL WATER AT ENFIELD.

A CURIOUS conflict of opinion has occurred in connexion with certain proceedings having for their object the closure of a surface well in the district of the Local Board of Enfield. Dr. Ridge, the medical officer of health, found the water suspicious from a chemical point of view, and still more suspicious because of the nature of the surroundings of the well. On this, proceedings were taken to secure the closure of the well; but the owner in the meantime procured an analysis by Dr. Tidy of water which professed to be that of the suspected well and of another well mixed together. The chemical results were all that could be wished, and the magistrates dismissed the case. The owner was then told that fresh samples would be taken, and this having been done, the analytical results were found not only to differ from the preceding ones, but, curiously enough, the water exhibited the presence of iron. In view of this, further samples were taken in the presence of several people, and this without any notice to the owner until the arrival of those who were prepared to take the water away with them. This time the analyst found chlorine equal in quantity to 18·45 grains of common salt in every gallon, 17·5 grains of nitric acid as nitrates, and no iron. The absence of iron in this sample points to the intentional addition of that substance with a view to a temporary purification of the water by oxidising or precipitating organic matter. The well in question is 16 feet deep; it lies in a district which has sewers with "open joints," and which have, in consequence, fouled the gravelly soil in which the well is sunk. Several of the house and closet drains were also recently found to be leaking through such joints. These circumstances alone amply suffice for the condemnation of the water-supply, and it is a matter of wonder how people can endeavour to show by chemical analysis that a water derived from a soil thus subject to the constant risk of pollution is really fit for domestic purposes. The freedom of individual samples from any indication of the surrounding contamination is a matter that should have no weight beside the fact that the source of the supply is one subject to constant risk of pollution. In this case, however, chemistry also came to the aid of the medical officer of health when the sample dealt with was collected under circumstances which were above suspicion.

CHILDREN IN WORKHOUSES.

THE care, treatment, and nursing of children in workhouses is a subject which at the present time calls for more attention at the hands of Local Government Board inspectors and the philanthropic public. After due allowance for the low physical standard of such children, and for their congenital tendency to disease, the excess of mortality that prevails among them is a subject that urgently demands inquiry and action. Inquiry, because Local Government Reports are silent upon the subject; and action, because much of this excess of mortality is assuredly preventable. It is only now and then that facts come to light helping us to call attention to the health condition of these unfortunate children; this makes it all the more necessary not to miss such opportunities. It appears from the last two weekly returns of the Registrar-General, that during the fortnight ending on the 4th inst. no fewer than fifteen children, most of them illegitimate, died from measles in the Camberwell Workhouse, Gordon-road, Peckham. It will be interesting to learn the number of infants in this workhouse, the number attacked by measles, and also whether this startling mortality will be the subject of a Local Government Board inquiry, with a view to ascertaining the kind of treatment and nursing which workhouse children receive on the occasion of such an outbreak of epidemic disease as that now prevailing in the Camberwell Workhouse.

MAD DOGS AT LARGE.

THE inhabitants of Sheffield seem to have been lately thrown into a state of consternation owing to mad dogs wandering in the streets. It is reported that special precautions have been taken by the police, and many dogs destroyed. These precautions are praiseworthy in themselves, but we doubt if they will prevent a recurrence of the danger. There can be no doubt that every dog roving at large, unattended, and "without visible means of subsistence," should be arrested as a rogue and vagabond, but the wholesale destruction of these waifs and strays seems unnecessarily severe. What we would suggest is that the number of places of refuge, or "dogs' homes," be extended. Greater facilities would then be given for watching suspicious characters, and for owners to claim their lost property. But these are cases which require peremptory treatment. If a dog is mad, it is worse than valueless to its possessor, whilst it is dangerous to every living being with whom it comes in contact. This might afford some reason, perhaps, why policemen should be armed with revolvers. It is not always easy, however, for the laity to tell whether a dog is the subject

of rabies, or merely gifted with vicious propensities. The necessary knowledge too often only comes of experience, and the vagrant cur runs fancy free until it has fleshed its envenomed teeth in some hapless passer-by. Save in a few isolated cases, where canine madness first shows itself in a fortuitous and unprovoked outburst of hostility towards an unsuspecting individual, the premonitory symptoms are sufficiently marked to arouse suspicion and point to danger. Restlessness, loss of appetite, and perversion of the affections are amongst the number. It is not feasible to educate the public in these matters by practical demonstration, but much may be done by way of warning and advice. A code of instructions might be drawn up and circulated by the local authorities, which would be of incalculable value to the community. It may be contended that such a procedure would arouse needless alarm, and condemn many an unoffending dog to a premature death; but against such an objection is the certainty that a number of human lives would be spared the perils of a terrible disease.

INTERNATIONAL HEALTH EXHIBITION.

DR. FELICE SANTINI, medical officer of health of the Royal Italian Navy, who was appointed by the Italian Government commissioner to the International Health Exhibition, has just published his report to the municipality of Rome.[1] He draws special attention to the excellent organisation of the Metropolitan Asylums Board, and the work done by them and the St. John Ambulance Association, and gives illustrations of the various ambulance carriages and stretchers used by these associations, together with a map showing the hospitals in connexion with the Metropolitan Asylums Board and diagrams of the hospital ships *Atlas*, *Endymion*, and *Castalia*, which are moored in the Thames. Dr. Santini was much impressed with the excellent idea of forming a hygienic library in connexion with the Exhibition, and brings to the notice of his Government and the municipality of Rome the services of Mr. Carl A. Thimm, the librarian, who so efficiently arranged and catalogued the voluminous publications contributed by Italy.

VOLUNTEER MEDICAL STAFF CORPS.

THIS corps, although enrolled only on April 1st, put in an appearance at the Brighton Review. Two companies, about fifty strong each, paraded at Wellington Barracks on Good Friday morning in full marching order, and, taking train at Victoria, accompanied the marching columns. No. 1 Bearer Company, under the command of Surgeon-Major Cantlie and Acting Surgeons Leech, Fletcher, and Willett, accompanied No. 7 column, under the command of Col. Sir Lloyd-Lindsay, V.C., and billeted at Burgess-hill. No. 2 Bearer Company, under the command of Surgeon-Major Norton and Acting Surgeons Huzzey and Raw, accompanied No. 2 marching column, and billeted at Newick. On Saturday the companies followed the troops over the downs, and had some rough work with the waggons. The ambulance waggons of No. 1 Bearer Company were blocked for three hours by a transport waggon, which had broken down on a narrow road over the hill. The bearers carried the stretchers over hill and dale for four miles to keep touch with the troops, and only by a forced march were they able to return to pick up their waggons and join the troops in the march into Brighton. No. 2 Bearer Company had to take the horses out and pull the waggons up the downs. At the headquarters of the corps at Brighton a temporary hospital of eight beds was opened, and as many as fifty-three patients were treated between Saturday night and Monday morning. The appearance of the new corps at the march past on Monday was the subject of much congratulation and cheering. The Duke of Cambridge, after the march past, rode up to the head of the column and complimented the corps on its appearance and efficiency. Surgeon Cross, Grenadier Guards, acted as commanding officer, and Surgeon Pearse as his staff officer. Lieutenant McLure acted as adjutant during the march. On the day of enrolment of the Volunteer Medical Staff Corps, an inauguration service was held at the Chapel Royal, Savoy, by the Rev. R. Westhorpe, Warden of Charing-cross Hospital and Chaplain of the Corps. About 180 attended.

[1] L'Igiene Pubblica e Privata e la Didattica alla Esposizione Internazionale d'Igiene in Londra, 1884. Rapporto all'onorevole Municipio di Roma, del Dottor Felice Santini. Roma: Fratelli Bencini. 1885.

THE METROPOLITAN BOARD OF WORKS AS A THEATRE LICENSING AUTHORITY.

THE Metropolitan Board of Works has politely asked the Lord Chamberlain whether he does not think it would make a better licensing authority than he has proved himself, and offered, "if his lordship agrees with this view," to take over the duty. We shall be curious to hear what the Lord Chamberlain thinks of this proposal. If he is wise he will hasten to wash his hands of the business. Meanwhile, will the Metropolitan Board of Works do the work better? And how about the licensing of stage plays? Does the Board propose to take that over also?

REPORT OF THE BERLIN HYGIENIC EXHIBITION.

WE have received a copy of the introduction to the first volume of the Report upon the German Health Exhibition, held at Berlin in 1883. On the close of the exhibition the task of editing this Report, which should survey the whole nature and scope of the exhibition, was placed in the hands of Dr. Paul Börner, who has prefixed to it an introduction detailing the steps taken to promote the exhibition, which was completed and ready for opening when destroyed by fire in 1882. Within twelve months the building was reconstructed on an improved plan; and a description of the building is given, with a brief history of the exhibition from its opening to its close. From the table of contents to the volume it is seen that the descriptive articles of each department are contributed by experts; and the work should therefore have a special and permanent value.

SHOULD AN INQUEST BE HELD?

MR. H. GOTOBED, the Cambridge borough coroner, recently held an inquest on a woman who had died suddenly of heart disease, and gave as his reason for so doing that about two years ago Lord Chancellor Selborne admonished a coroner for neglecting to institute an inquiry into the cause of death of a person found dead in bed. Lord Chief Justice Jervis held that, unless there was reasonable ground of suspicion that the person came to his death by violent and unnatural means, there was no occasion for the interference of the coroner. On the strength of the report of the recent inquest, we fail to see the discrepancy between the legal authorities cited by Mr. Gotobed. A person being found dead in bed, the presumption is that death arose from natural causes; but it would never do to grant a certificate on such wholly insufficient grounds. If, on the other hand, a person was known to have suffered from heart disease, and was subsequently seen to fall down in a fatal swoon, this, together with the circumstantial evidence, might warrant the coroner's decision not to order an official inquiry. At the same time, we contend it is highly desirable that the exact cause of death should, where possible, be determined in every case. Anything short of this obviously allows of mistakes, and possibly in some instances leads to

a miscarriage of justice. The records of our judicial proceedings clearly show that what has *à priori* been thought satisfactory proof of natural death has been really consistent with criminal intent and deeds.

OPPOSITION TO THE POISONS BILL.

THE opposition to the provisions of the new Poisons Bill continues with unabated vigour. In an article devoted to the subject in one of the trade journals, it is pointed out that the powers assigned to the Pharmaceutical Society are amply sufficient if only they were exercised with discretion. The omission in the Bill to define the term "poison" has been severely criticised, although it must be confessed that the difficulties in the way of a satisfactory definition are very great. Almost any substance capable of being absorbed into the circulation or of mechanically irritating the mucous membrane to a sufficient extent might cause death, the quantity necessary to induce a fatal result being one of degree only. A case is referred to of a gentleman who was poisoned by eating jugged hare in an advanced stage of decomposition. It is supposed that a fragment of bone caused an abrasion of the mucous membrane of the mouth or throat, and that this sufficed for the absorption of septic material. In another instance a young lady succeeded in destroying herself by swallowing a pound and a quarter of common table salt. Under the proposed Act it is probable that vendors of patent medicines containing active ingredients will incur a certain amount of responsibility, although the clauses dealing with the subject are so vaguely worded that it is difficult to foretell what will be the practical result of their operation. It is probable that the Bill, if not thrown out altogether, will be considerably modified in Committee.

PREVENTABLE DISEASES IN TOTTENHAM.

THE Tottenham Sanitary Association, which for many years past has done good work in stimulating sanitary work in its district, now publishes its eleventh report—namely, that for 1884. In a population of some 70,000, the death-rate was 16·45 per 1000. Typhoid fever and diphtheria were both excessive in their fatality, the last disease being three times more fatal than it was during the same period in London. As a result of this occurrence, special efforts are being made by the sanitary inspector to elicit information as to the state of the drains, their disconnexion and ventilation, whenever fatal zymotic disease occurs. This is good in its way; but it would be far better if, in addition to such action after the occurrence of the very result which should be avoided, the authority were to organise such a system of house-to-house inspection as would lead to the adoption of measures which would prevent the occurrence of diseases due to faulty drain connexions.

PERFORATING ULCER OF THE HAND.

THOUGH perforating ulcers occurring in the course of tabes dorsalis have their usual seat in the foot, there seems no reason why the hand should not be similarly affected. M. Terrillon showed a case of perforating ulcer of the palm of the hand at a recent meeting of the Société de Chirurgie. The ulcer was situate at the junction of the ring finger with the palm. The patient was a porter, and the subject of tabes dorsalis. M. Charcot did not hesitate to regard the ulcer as of dystrophic origin; pains and tinglings were experienced by the patient along the course of the ulnar nerve. A zone of anæsthesia was detected all round the ulcer. M. Nicaise inclined to the opinion that the ulcer was merely a corn which had become fissured, for the epidermis and cutis were thickened, whereas in perforating ulcers the cutis is thinned and even perforated.

ANTHRAX IN BERMONDSEY.

FROM time to time during the past few years cases of fatal anthrax have been reported at Guy's Hospital, arising in connexion with the Bermondsey tanneries. The most recent case occurred last week. The subject was a labourer, aged thirty-eight, employed in handling hides at a wharfinger's. Less than four days before his death he complained of feeling sick, and noticed a small pimple on the side of the neck; and the next day he presented himself at the hospital with well-marked symptoms of malignant pustule. At the inquest Mr. Langham, the coroner, drew public attention to the great importance of persons infected with the poison making early application for hospital treatment. The verdict of the jury, "Natural death from blood-poisoning," seems to us to have been scarcely sufficient; for it cannot be too widely known that the disease contracted from these infected hides is a definite and specific affection, and that every precaution should be taken to protect workmen against contamination.

EXPERIMENTS ON SOLDIERS' RATIONS.

EXPERIMENTS are being made in Munich, Mayence, Munster, and elsewhere, with companies specially formed of the strong men of different regiments. The men selected are obliged to submit for a fortnight to a strict campaigning diet, and during this period have to go through field exercises and route-marching for six hours daily in full marching order. Before and after every march out each man is carefully weighed. He receives daily a regulated quantity of a minutely described dietary—e.g., in Mayence, biscuit, coffee, pea-sausages *(Erbswurst)*; in Munster, rye bread, brandy, and *Erbswurst*; the Munich *menu* has so far remained a secret. The men are constantly and closely watched, so that it is impossible for them to obtain any other food or drink than that laid down. The object of these experiments is to determine how long men will remain fit for work on such diet, and also to institute a comparison between the different diets tested.

ANTISEPTICS AND ERYSIPELAS.

FROM a statistical study of the surgical cases which have been under his care during the past five years, M. Polaillon has come to the conclusion that Listerism and carbolic dressings generally do not diminish the liability to the occurrence of erysipelas, though they lessen the virulence of the disease. In his experience women are more frequently affected than men, but the latter occupy the more salubrious ward. Sometimes the erysipelas occurred in isolated cases. Erysipelas was more frequent during the cold and wet months. Carbolised dressings, he avers, certainly attenuate the virulence of erysipelas. He has seen epidemics spread from patient to patient rapidly, yet making but few victims, and those only whose constitutions were enfeebled by long-lasting disease.

BALNEOLOGICAL CONGRESS.

THE seventh annual Congress of the Balneological Section of the German Therapeutical Society was held on March 14th and 15th at Berlin, under the Presidency of Professor Liebreich. Dr. Schott of Nauheim spoke regarding the importance of cutaneous resorption in connexion with the effects of baths. Dr. Grödel raised the question whether special balneo-therapeutical methods could be defined for various forms of spinal affections, but the discussion which ensued bore unfavourably on the possibility of such a treatment being perfected. Professor Eulenberg of Berlin spoke on the subject of electric baths, and the mode of their application to therapeutical purposes.

THE LONDON UNIVERSITY AND MEDICAL DEGREES.

WE understand that the Senate of the University of London have consented to receive, on the 29th inst., at 4.45 P.M., a deputation from the Metropolitan Counties Branch of the British Medical Association in reference to the question of granting medical degrees to London medical students.

THE GENERAL MEDICAL COUNCIL.

THE General Medical Council is summoned to meet on Tuesday, May 12th. The Executive Committee will meet on the preceding day, to arrange the order of business, &c.

THE DEATH OF LORD CAIRNS.

WE have authority for saying, contrary to the statement of some newspapers, that Sir William Gull never saw Lord Cairns medically, and was never requested to see him.

THE BICHLORIDE DOUCHE IN OBSTETRICS.

THE *New York Medical Record* reports that Dr. Hulbert, of St. Louis, stated, at a meeting of the St. Louis Medical Society, that he had salivated five patients with a bichloride solution (1 in 3000) given as a vaginal douche twice a day. No particulars are given, but it is evident that this agent, though a very effective antiseptic, will have to be used very carefully.

DR. J. F. STEVENSON, J.P., has just resigned the post of physician to the Birkenhead Borough Hospital. He was appointed as honorary surgeon to the institution in 1848, and having filled that office for a period of fifteen years, was appointed to the office which he has just resigned. Dr. Stevenson will continue his connexion with the charity as consulting physician. The committee have formally recorded their high sense of the valuable and efficient services rendered by Dr. Stevenson for this period of upwards of thirty-six years. Dr. Stevenson is to be congratulated, as it is not given to many members of even the medical profession to complete so long a term of gratuitous daily work.

SOME very exaggerated reports having been circulated concerning the prevalence of small-pox at Southend, it is well to mention that the case which is supposed to have been the first was not small-pox at all, but pleurisy; also that the sexton who was employed at the funeral, and who really died of small-pox shortly afterwards, caught the disease from his son, who was found to be suffering from it on his arrival from near London, and who has now recovered. We believe that, owing to the isolated position of the house and the care exercised by the medical officer of health, no other cases have occurred.

A CONTROVERSY on the subject of undue pressure in the public schools of America has been proceeding for some time, and from the *New York Daily Tribune* of the 24th ult. it now appears that the advocates of reform are steadily gaining ground, it being expected that the much-needed revision of the course of study and method of examinations in American schools will be substantially accomplished before the beginning of a new school year.

AN outbreak of English cholera, causing considerable alarm, is reported from Mountain Ash, where many people are affected in one part of the district called Caegarw, and one man has succumbed to the malady.

AT the Teachers' Conference at Norwich on the 8th inst., Mrs. Burgwin (Southwark) read a paper on over-pressure in schools, which she described as work against time to secure payment by results—a system injurious to teachers and torture to children, who were made disgusted with learning. She advocated the abolition of all grants under certain conditions, considering that education should not be hurried. A resolution was adopted to petition Parliament to appoint a Royal Commission to inquire into the existence, causes, and extent of over-pressure, it being felt that a departmental inquiry would not be satisfactory.

AT Jativa, in the province of Valencia, seventy persons have been attacked during the past fortnight by a disease resembling cholera. About half the cases ended fatally, and although several physicians have hesitated to pronounce the epidemic to be cholera, others who were sent to inquire into the outbreak affirm that it is that disease, and precautions have been taken to prevent its spread. The patients and their families have been put under canvas, and the houses where deaths have occurred have been disinfected.

MR. M. A. ADAMS, F.R.C.S., has devised a card containing the leading facts of importance in the record and investigation of contagious diseases. It embodies a neatly drawn-up chart to indicate the presumed normal periods of latency, premonitory fever, duration of pyrexia, and of the infectiveness of such diseases; and, being of convenient size, it should prove of some service. It is issued by Messrs. Churchill.

THE Paris correspondent of the *Record* says:—"A remarkable instance of confraternity has just occurred at Carcassone at the funeral of an eminent doctor, a Roman Catholic, who behaved most nobly during the last cholera epidemic. Three discourses were pronounced at the cemetery, one by the prefect of the Department, one by the president of the Doctors' Association, and one by the [Protestant] pasteur of the place, the Rev. Ad. Monod."

MR. ARNOLD TAYLOR, of the Local Government Board, has been holding an inquiry in the Ramsgate Town Hall concerning the loan of £20,000 required for the completion of the drainage and for the construction of new outfall works. Various difficulties and objections having been overcome, the opposition to the proposed scheme was nominal, and Mr. Taylor signified his intention of reporting favourably on the plan.

THE fourteenth Congress of the German Surgical Society met at Berlin on the 8th inst., under the presidency of Professor Langenbeck, who announced, to the manifest approval of the members, that the Committee had been pleased to nominate as honorary members Sir James Paget and Sir Joseph Lister.

WE are asked to state that applications for the appointment of Assistant Physician at Guy's Hospital, rendered vacant by the promotion of Dr. Frederick Taylor to the Physicianship, should be sent in on or before Thursday, the 30th inst.

WE learn that, at the unanimous request of the medical staff of the Paddington-green Children's Hospital, the post of senior physician will be filled by the appointment of Dr. Lauder Brunton.

THE eighth edition of Erichsen's Surgery is being translated into Spanish, and is appearing in monthly parts.

DR. ANGEL MONEY has been appointed Assistant Physician to the Hospital for Sick Children, Great Ormond-street, in the place of Dr. Barlow, promoted to the post of Physician to the institution.

IN a letter to the Lord Chancellor, dated April 6th, the Earl of Shaftesbury has expressed his decision to resign his seat on the Board of Commissioners in Lunacy.

THE DRAMATIS PERSONÆ OF THE TERCENTENARY FESTIVAL OF THE UNIVERSITY OF EDINBURGH.

WE have good news for the alumni and graduates of the Edinburgh University. The event of the Tercentenary was one not likely to be forgotten. In itself it was one of the most remarkable gatherings of the men of light and leading in history. It produced, too, the "Story of the University," by the lamented and accomplished principal, Sir Alexander Grant, which is in itself guarantee that it will not be allowed to be forgotten. But as if this were not enough, a most exquisite volume of "Portraits of the High Officers and Professors of the University of Edinburgh at its Tercentenary Festival" has been published at the University Press by Messrs. T. and A. Constable. The volume before us, which is so charming as to disarm all criticism, is in a quarto form; but we gather that there are a certain number of folio copies to be had by those still more luxurious in their literary tastes. For ourselves, we are well content with and very grateful for the quarto form, which makes one of the pleasantest and most valuable additions to a library which we have seen for many days, and which cannot be too much praised either as regards the work of the printer, the compiler, or the artist. The artist is Mr. William Hole, A.R.S.A., who had already given some artistic intimations of the vivid impression made on his mind by the chief actors of the Tercentenary. In the forty or fifty portraits now presented to the public, the art of etching appears to the greatest advantage, and will hand down to a remote time a representation of the present professors. Even those learned professors whose physical qualities do not facilitate the etcher's art come out in style so natural and life-like as to be most interesting. And in the case of a few of the portraits, the result is most effective, as in that of Sir Stafford Northcote, of the lamented Principal, of Professor Blackie and his successor, of Professor Masson (in his slippers, sitting cosily by his fireside, and, low be it spoken, in the obvious enjoyment of his meerschaum), of Professor Turner, of Professor Fraser, of Professor Douglas Maclagan, of "John Chiene," of Professor Grainger Stewart, of Professor Rutherford, and of Professor Greenfield. Perhaps the most striking piece of art in the book is the portait of Professor Giekie, sitting on a boulder, a hammer in one hand and a geological specimen in the other style. The interest of the volume is greatly, if pathetically, enhanced by a frontispiece entitled "*Umbræ Quædam*," and giving the heads of professors and others recently dead who have shed lustre on the university, and whose fame still gives a strange fascination to the school—notably Sir William Hamilton, John Goodsir, David Brewster, James Syme, J. Y. Simpson, J. Hughes Bennett, R. Christison, J. H. Balfour, T. Carlyle, and others. Though the etchings and the general style of the book are the chief attractions of this happily conceived work, we should do great injustice to its promoters if we did not say a word in praise of the biographical sketches which are attached to each portrait. They are remarkably well done, occasionally perhaps betraying a little too much local complacency, but generally most readable and instructive. We cannot too strongly express our pleasure in possessing such a memento of so eventful an occasion. The only qualification of our satisfaction we have to make in our announcement of the book is that the number of copies is, we presume necessarily, limited. The impression for sale of the folio copies is 100, that of the quarto 750. *Beati possidentes!*

INTERNATIONAL CONGRESS OF HYDROLOGY AND CLIMATOLOGY.

THE first International Congress of Hydrology and Climatology will be held at Biarritz in October, 1886. Amongst the principal questions which will be brought before the members of the Congress are the following:—The Influence of the Phenomena of the Air on Mineral Waters, the Electrical Phenomena which manifest themselves in the presence of Mineral Waters, the Combinations which form Sulphur in the Waters termed Sulphur Waters, the Differences of Action between Fresh and Salt Water in Hydrotherapy, the Hygienic and Dietetic Rules to be observed whilst undergoing a course of Thermal Treatment, the daily Variations of Temperature in Sanitary Stations, General Characters of the Geological Constitution of the Pyrenees, the Hygienic Conditions which ought to prevail at Summer and Winter Health Resorts, the Influence of Sea Air upon Scrofulous Affections, the Influence of Winds, Quarantine by Land and Sea, &c. The Congress will last for eight days, and excursions to various places of interest in the neighbourhood will take place. The honorary president is the Minister of Commerce, and the acting president will be Dr. Durand-Fardel, the post of general secretary being filled by Dr. F. Garrigon.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Worcester Urban District.—In submitting his eleventh annual report to the Town Council of Worcester, Dr. Strange gives marked attention to cleansing of ashpits and cesspits, to the care of sewers and house-drains, and to the supply of drinking water to the inhabitants; and he does so with special reference to a somewhat heavy visitation of enteric fever from which the city has suffered. In the first place, Worcester still exhibits some of the old huge ashpits and cesspits, receptacles which were contrived in days when sanitary authorities were all but unknown, and when scavenging was a thing to be carried out as seldom as possible. Now, however, we know that these accumulations are hurtful in the extreme, and it should be a first object of the authority to get rid of such nuisances, especially in view of the risk they are to health. Much is, fortunately, being done in this direction, and it is to be hoped that there will be no need to recur to them in future reports, except as barbarisms of the past. As to the sewers, it is stated that complaints are made with respect to the emanations from the ventilators; but we can hardly agree with Dr. Strange that, inasmuch as these ventilators are only discharging their proper function, it is unwise to complain of them. Sewer ventilators should not stink. If they do, they are either not sufficiently numerous, or the sewers do not properly cleanse themselves, or else offensive house-drains are connected with them and foul them. If the sewers and house-drains are properly constructed so as to contain no stagnant contents, and if the ventilators are so numerous that a large number of them act as fresh-air inlets to dilute the sewer air before it escapes, then nuisance should not arise. But we fear that faulty conditions as to this exist in Worcester; for Dr. Strange talks of sewer air being forced back into dwellings unless it can escape into the streets. Such a forcing back should be impossible if there were an absolute break between the interior of the houses and the interior of the drains. In many hundred cases this break has now

been effected in Worcester, and it is to be hoped that it will soon be universal. The detailed account given as to the water-supply to the city, now derived from the Severn, raises some very important considerations. As matters now stand, the Severn is liable to pollution by sewage and other organic matter after a heavy rainfall. Thus, the sewage of Kidderminster, during the great enteric fever epidemic there, got into the Severn fourteen miles above the Worcester intake, and the question now being dealt with is whether Worcester is to endeavour to remedy its river supply and improve its method of filtration, or to resort to an artesian well. In seeking advice, the opinion of the borough analyst has been sought, especially as to whether filtration would secure the inhabitants against "this great source of danger" (i.e., "pollution by the germs of disease"), and he has answered, "If efficiently carried out, I believe it does." What this belief is based on we do not know, but we are quite certain that this view should not be acted on as regards a town water-supply. No such filtration as can be carried out by Worcester is likely to have the effect they wish to attain; and if the river is to remain subject to any such risks as hitherto, we should counsel its abandonment as a source of water-supply. The annual death-rate in Worcester for 1884 was 20·9 per 1000. Thirty-two cases, chiefly of enteric fever, were admitted into the Brabourne Hospital.

Lewes Urban District.—Lewes has for some years past had a satisfactory death-rate. Last year it reached 15·9 per 1000, somewhat in excess of the two previous years. Consumption is a somewhat fertile source of death, and we fear that the situation of the town at the foot of a chalk range in a river valley is a main cause in producing this result. The isolation hospital continues usefully to fulfil its purpose. The numbers admitted are not large, but the admissions prevent the extension of infectious disease, and, as Mr. Braden says, it would be impossible to say what mischief the thirty cases admitted since its construction would have brought about had they not been isolated.

Surbiton Urban District.—This suburban district enjoys a small death-rate. It was 10·8 per 1000 in 1883 and 11·9 in 1884, the rate for England and Wales during the latter year being 19·6. The zymotic rate is also low—namely, 1·4 per 1000. Infantile diarrhœa, too, which may be regarded as affording a valuable criterion of the healthiness of a place, only causes about 2 or 3 deaths per annum; in short, as a zymotic affection it is practically absent. Well water is, however, still resorted to, analysis almost invariably being such as to call for its abandonment. The ventilation of the sewers is engaging the attention of the authority, and a number of high shafts are being erected. There is as yet no hospital for infectious diseases. The neighbouring authority of the Kingston rural district have set an example as to this, and Dr. Coleman suggests inquiry as to whether Surbiton may share in its advantages.

Torquay Urban District.—The sanitary inspector for this district has issued a report showing the progress which has been made during the past year in the various matters coming within his cognisance, and it is certainly a record of very substantial advance. The detailed account of current work relating to such matters as the ventilation of drains and soil-pipes, drain disconnexions, closure of wells, disinfection of rooms, &c., relates to 4639 improvements. In addition to this as many as 545 new houses have been overlooked during the course of their erection. The change throughout the town from old, unventilated, choked, clay-jointed, untrapped drains to efficient, self-cleansing, and well ventilated conduits is in itself immense, and added to this work a large amount of incidental improvement has been effected in allied matters. Torquay aims at securing the reputation of being a real health resort, and such work as Mr. MacMahon gives an account of is eminently calculated to attain that end.

Belfast.—During the four weeks ending Feb. 21st the total births registered were 493, and the deaths 472, which latter included 216 deaths from lung affections. The average death-rate was, from all causes, 28 per 1000, from zymotic diseases 2·6, and from lung diseases 12·6. The general death-rate was a little higher than in January, though the rate from lung affections was 2 per 1000 less. Scarlatina still lingers amongst the population, but it is gratifying to learn that both typhus and enteric fevers have almost disappeared.

Cork.—During the four weeks ending the 21st ult. the births numbered 152, or a rate of 24·66; and the deaths 204, including 41 which took place in the workhouse. Excluding the latter, the mortality was equal to 33·09 per 1000. Compared with the corresponding return of last year, the death-rate has increased, and the birth-rate decreased.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN twenty-eight of the largest English towns 5450 births and 3937 deaths were registered during the week ending the 4th inst. The births were 362 below, while the deaths exceeded by 310 the average weekly numbers during 1884. The annual death-rate in these towns, which had been equal to 23·5 and 23·2 per 1000 in the preceding two weeks, further declined last week to 23·1. During the thirteen weeks ending last Saturday the death-rate in these towns averaged 21·9 per 1000, against 24·7, the mean rate in the corresponding periods of the nine years 1876-84. The lowest death-rates in these towns last week were 15·7 in Leicester, 17·8 in Bradford, 19·1 in Brighton, and 19·8 in Wolverhampton. The rates in the other towns ranged upwards to 32·6 in Norwich, 33·7 in Newcastle-upon-Tyne, 34·3 in Preston, 34·7 in Oldham, and 40·4 in Sunderland. The deaths referred to the principal zymotic diseases in the twenty-eight towns were 466, against numbers steadily increasing from 377 to 451 in the preceding five weeks; they included 173 from measles, 130 from whooping-cough, 45 from "fever" (principally enteric), 33 from scarlet fever, 32 from small-pox, 27 from diphtheria, and 26 from diarrhœa. No death was referred to any of these diseases in Derby last week, whereas they caused the highest death-rates in Norwich, Newcastle-upon-Tyne, Cardiff, and Sunderland. The highest death-rates from measles occurred in Bristol, Newcastle-upon-Tyne, Cardiff, and Sunderland; from whooping-cough in Oldham, Bristol, and Preston; from scarlet fever in Preston and Newcastle-upon-Tyne; and "fever" in Plymouth and Norwich. Of the 27 deaths from diphtheria in the twenty-eight towns 16 occurred in London and 2 in Norwich. Small-pox caused 54 deaths in London and its outer ring of suburban districts, 2 in Manchester, 1 in Birmingham, and 1 in Leeds. The number of small-pox patients in the metropolitan asylum hospitals, which had been 830 and 865 on the preceding two Saturdays, further rose to 879 at the end of last week; 141 cases were admitted during the week, against numbers increasing from 94 to 179 in the previous four weeks. The Highgate Small-pox Hospital contained 90 patients on Saturday last, 25 cases having been admitted during the week. The deaths referred to diseases of the respiratory organs in London, which had been 487 and 448 in the preceding two weeks, rose again to 478 last week, but were 65 below the corrected weekly average. The causes of 100, or 2·5 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Bradford, Bolton, Wolverhampton, and Plymouth. The largest proportions of uncertified deaths were registered in Oldham, Preston, Sheffield, Halifax, and Hull.

HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 24·2 and 23·3 per 1000 in the preceding two weeks, rose last week to 25·0, and exceeded the rate last week in the twenty-eight large English towns by 1·9. The rates in the Scotch towns ranged from 15·2 in Leith and 17·0 in Edinburgh and Aberdeen, to 30·8 in Paisley and 31·5 in Glasgow. The 600 deaths in the eight towns included 34 from whooping-cough, 23 from measles, 11 from scarlet fever, 6 from "fever" (typhus, enteric, or simple), 5 from diarrhœa, and not one from small-pox; in all, 84 deaths resulted from these principal zymotic diseases, against 85 and 73 in the preceding two weeks. These 84 deaths were equal to an annual rate of 3·4 per 1000, which was 0·7 above the mean rate from the same diseases in the twenty-eight English towns. The deaths from whooping-cough, which had been 35 and 32 in the previous two weeks, were 34 last week, of which 22 occurred in Glasgow, 4 in Edinburgh, and 4 in Dundee. The 23 fatal cases of measles showed an increase of 8 upon the number in the

previous week, and were all returned in Glasgow. The 11 deaths from scarlet fever also showed an increase upon the number in the previous week, and included 5 in Paisley, 3 in Glasgow, and 2 in Edinburgh. The 6 deaths referred to "fever" corresponded with the number in the previous week, and included 3 in Edinburgh and 2 in Greenock. The deaths from acute diseases of the respiratory organs in the eight towns, which had been 124 and 122 in the previous two weeks, rose to 130 last week, and exceeded the number in the corresponding week of last year by 22. The causes of 103, or 17 per cent., of the deaths in the eight Scotch towns last week were not certified.

HEALTH OF DUBLIN.

The rate of mortality in Dublin, which had been equal to 39·5, 34·6, and 40·4 per 1000 in the preceding three weeks, declined again to 33·6 in the week ending the 4th inst. During the thirteen weeks ending last Saturday the death-rate in the city averaged no less than 34·0 per 1000; whereas in the same period the rate did not exceed 21·6 in London and 20·0 in Edinburgh. The 227 deaths in Dublin last week showed a decline of 46 from the exceptionally high number in the previous week, and included 24 which were referred to the principal zymotic diseases, against 30 and 32 in the preceding two weeks. Of these 24 deaths, 13 resulted from measles, 5 from "fever," (typhus, enteric, or simple), 4 from diarrhœa, 2 from scarlet fever, and not one either from small-pox, diphtheria, or whooping-cough. The annual death-rate from these principal zymotic diseases was equal to 3·5 per 1000; in London and Edinburgh the rates from these diseases last week were equal to 2·6 and 2·1 respectively. The fatal cases of measles in Dublin, which had been 16 and 12 in the previous two weeks, were 13 last week. The deaths referred to scarlet fever and "fever" were respectively 5 and 1 below the numbers in the preceding week. Three inquest cases and 3 deaths from violence were registered within the city; and 86, or 38 per cent., of the deaths were recorded in public institutions. The deaths both of infants and of elderly persons showed a considerable decline from the high numbers in the previous week. The causes of 26, or 11 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

ARMY MEDICAL SCHOOL.

THE fiftieth session of the Army Medical School was opened at Netley on the 2nd inst. Forty-five surgeons on probation for the British army and five for the Indian army have joined. In consequence of the urgent need for medical officers, these gentlemen will only remain for two months instead of four, their places being taken by a second batch, who will join early in June and be dismissed in the beginning of August. The introductory address was delivered by Professor Aitken, F.R.S., who gave a philosophical lecture dealing with the application of the Darwinian hypothesis and the evolution of disease. The Director-General, Dr. Crawford, was present, and addressed some words of counsel to the surgeons on probation. Sir Joseph Fayrer, K.C.S.I., Surgeon-General Murray, Colonel Bell, and the officers of the school and hospital staffs were also present.

Several lady nurses from the Guards Hospital in London have left for Suez for duty with the Guards' field hospital at that place.

It having been decided to separate the duties of the medical administration of the troops stationed in the Home and Woolwich districts, which have hitherto been vested in one officer, Surgeon-General Sir James Hanbury, who was principal medical officer in Egypt during the campaign of 1882, takes over the medical charge of the Home district, and Brigade Surgeon T. Rudd that of the Woolwich district.

ADMIRALTY.—In accordance with the provisions of Her Majesty's Order in Council of April 1st, 1881, Staff Surgeon Alfred Hubert Kelly, B.A., M.D., has been allowed to withdraw from Her Majesty's Naval Service, with a gratuity.

The following appointments have been made:—Staff Surgeon Edward E. Mahon, to the *Bacchante;* Staff Surgeon Herbert M. Ellis, to the *Sapphire;* Staff Surgeon Robert W. Williams, to the *Pegasus;* Surgeon H. G. Jacob, to the *Racer;* Surgeon J. M. Rogers, to the *Agincourt;* J. W. Grene, to be Surgeon and Agent at Crookhaven; Fleet Surgeon James Flanagan, to the *Cambridge;* Fleet Surgeon Garland W. L. Harrison, to the *Northumberland;* Surgeon Herbert W. G. Doyne, to the *Bacchante;* Surgeon James C. F. Whicher, to the *Agincourt;* Surgeon Henry G. T. Strickland, to the *Victor Emanuel;* and Surgeon J. D. Henwood, to Plymouth Hospital.

A trained naval sick-berth staff is being established, and boys, who will be medically examined as to fitness for the service, will be selected from Greenwich Hospital School, the mercantile marine, and other sources. After completing a year's service in a training ship they will be sent to Haslar Hospital, where they will receive instruction in elementary anatomy, bandaging, in dressing wounds, and such other exercises as will enable them to render first aid to the wounded afloat and ashore. After performing these preliminaries the candidates will undergo an examination, and if found qualified they will be rated as sick-berth attendants with Admiralty approval. A notice has also been published that, pending the introduction of the new scheme, a few young men, whose age is between eighteen and twenty years, will be trained as nurses. They will have, if fit for the duties, all the advantages of the new system.

Correspondence.

"Audi alteram partem."

"STRANGULATED OMENTAL HERNIA."

To the Editor of THE LANCET.

SIR,—Some time ago Mr. Rushton Parker published a short work on "Abdominal Hernia," in which he questioned the usual doctrine that the strangulation of omentum only in a hernia will produce the same symptoms (though possibly less severe) as are produced by strangulation of the intestine, and he repeated his views in your columns on May 17th, 1884. He called attention to the fact that in my work on the "Principles and Practice of Surgery" I had supported the usual teaching, although I thought it right to call attention to the circumstance that the ligature of the omentum produces no such symptoms. Mr. Parker believes that the old doctrine is erroneous, and that the symptoms, in cases where strangulation is believed to have occurred in herniæ, which are really epiploceles—i.e., purely omentum—are due either to obstruction resulting from the dragging of the omentum on the colon, or to peritonitis, or to purely functional obstruction of intestine due to some other cause, and unconnected with the epiplocele except by simultaniety of occurrence;[1] whilst he believes that there is another class of cases in which the hernia is not really omental only; but that a piece of bowel has been in the sac, but has somehow got reduced either during the operation, or by the taxis just before the operation. I replied to Mr. Parker's criticisms in a letter which you published on August 4th, 1883, in which I hesitated to accept the second hypothesis (that of the reduction of previously strangulated bowel). As, however, a case has lately occurred in my own practice showing the reality of the fact, I hasten to put it on record in justice to Mr. Parker, as well as in consideration of the interest of the surgical question itself.

The heads of my case are briefly these:—An old man (aged seventy-three) was admitted into St. George's Hospital during the night of March 19th for umbilical hernia, with constipation and vomiting. I was accidentally absent, and a colleague was called in, who saw no reason to interfere by operation. Nor did I when I saw the man next day. He had had the rupture for two years. Latterly he had had a bad cough, and the tumour had become larger. On the previous day, after a severe fit of coughing, he suddenly experienced great pain at the umbilicus, and increased swelling. He began to vomit soon afterwards. The vomiting, however, at first was almost entirely of the contents of the

[1] Of this last view Mr. Parker gives an example in the accompanying letter.

stomach, and seemed to be excited by his cough. I must not burden your space with all the particulars of the case. Gentle attempts were made to reduce the hernia, but with no effect, on March 20th, and I believe no serious effort at taxis was made on any subsequent occasion. The man went on in much the same way for three days; but then the vomit became obviously more "fæcal"—i.e., it was no longer from the stomach only but from the small intestines, and his strength began also to fail, so that it was clear that if not relieved he would die. At the same time, his chest was so full of rhonchi, and his heart's action so feeble, that I was unwilling to give an anæsthetic. On March 23rd the parts over the sac were frozen and divided, and the sac found tightly constricted. The stricture being freely divided, attempts were made to reduce the hernia; and these not succeeding, the sac was opened, and nothing found in it but congested omentum, which was removed after tying its stalk with a double catgut ligature. The vomiting continued, and the patient died eighteen hours afterwards. On post-mortem examination the omentum was found adherent, not to the neck of the sac, which was quite free, but to the parietal peritoneum inside the belly. The portion in the sac could not, therefore, have exerted any traction on the colon, nor was there any serious displacement or any loading of that portion of the bowel. But about four inches from the ring was found a knuckle of small intestine, which had obviously been recently strangulated, and is thus described by our curator, Mr. Shield:—"It was about two inches in length, congested, and claret coloured, and was terminated above and below by the dark narrow furrow, both discoloured and contracting the bowel, which is commonly seen in intestine reduced in hernia, and is unmistakable in appearance." The fresh appearance of the constrictions and the still congested condition of the bowel appear to me conclusive proof that the reduction of the constricted intestine must have taken place during the operation, eighteen hours before death, and not in the attempts at taxis three days before.

The case proves beyond reasonable doubt that Mr. Parker is *right in* believing that some of these cases are not cases of *pure epiplocele* at all, and that I was wrong in thinking *that an experienced* surgeon could not have reduced a small knuckle of bowel without being aware of the fact, or noticing an unoccupied portion of the sac from which the bowel had been reduced. It does not, however, convince me of the truth of Mr. Parker's opinion, that strangulation of omentum only cannot produce the symptoms which I have indicated, and I confess that I still hold the opinion stated in my book, in connexion with many other surgeons, who also have met with cases inexplicable to their minds in any other way, difficult, as it may be, to form a satisfactory theory of the occurrence. At any rate, I thought it my duty to ask you for space to record this case.

I am, Sir, yours truly,

Great Cumberland-street, April 6th, 1885. T. HOLMES.

To the Editor of THE LANCET.

SIR,—Mr. Timothy Holmes has had the great kindness to let me see the copy of his letter, in which he makes very handsome reference to me. Having myself found post-mortem evidence of previous intestinal replacement in fatal strangulated hernia that had been, or was capable of being, supposed to be mere epiplocele, I had the best grounds for believing that a similar condition of things could occur again. The combined circumstances that render this observation possible must be so rare that Mr. Holmes's independent confirmation lends to my contention a support without which many would fail to be impressed by it. After all, however, his case, like the one I referred to, merely shows how, in a certain rare, but always possible, class of cases, to avoid the fallacy of attributing to strangulated omentum symptoms really caused by strangulated intestine. I continue unshaken in the firm conviction that strangulation of omentum alone, *as* strangulation, can have no symptoms, seeing that the tightest ligature never produces them. Among the various explanations that can be given of the undoubted symptoms that are found in cases where omentum alone exists, and is supposed to be strangulated, I mentioned the occurrence of intestinal obstruction of the "functional" kind in persons who happen to also have an omental, though harmless, hernia. It is not a very uncommon thing to meet with patients who suffer from constipation, vomiting, griping, or vague abdominal distress. Such cases are remedied by fasting, by rest and warmth, and by the narcotic assistance of opium, alcohol, or both. In my pamphlet on "Abdominal Hernia" I asked, "Why such symptoms should not now and then occur to persons already possessed of a hernia?" They are, in fact, perfectly well known in old large herniæ, especially umbilical; and although the hernia of intestine is often, if not generally, at fault, even if not strangulated, by being materially hampered through adhesions, &c., still such symptoms have often nothing whatever to do with the hernia. It must be so, for surely persons do not require a hernia in order to get "bowel complaint," whether it be diarrhœa, constipation, or mild obstruction. Such being the case, it is contrary to common sense and clinical experience to put down such symptoms at once, and in every case, to the supposed strangulation of a previously long harmless omental hernia. Such a case I, not long ago, witnessed. On Dec. 22nd, 1884, I saw, in consultation with Mr. H. O. Thomas, an old lady of nearly seventy who had long had an irreducible omental femoral hernia. For two or three days previously she had had constipation, vomiting, furred tongue, loss of appetite, griping, and general abdominal distress. The hernia, moreover, had increased in size, but whatever its contents, it was not resonant on percussion. Taxis was very gently attempted under an anæsthetic, as well as without, but the hernia could not be in the least altered in bulk or shape. The case we both admitted to be consistent with the existence of functional obstruction of intestine, independently of the hernia; yet, knowing how insidiously strangulation of intestine occurs, without much addition to the hernial bulk, I felt that operation would be the wiser course to make sure. But Mr. Thomas rather held to the view that the hernia was not in this case in fault. So after ample discussion I agreed to his proposal to trocar the centre of the hernia for exploratory purposes. The only issue was blood-stained serum, without odour at all, on which it was agreed that we had not reached intestine and that the patient could fairly be left to medical treatment. A little morphia was given under the skin and the mouth merely moistened with necessary liquid, the result being entire cessation of symptoms and speedy recovery. Cases like this show that the whole casuistry of the subject is rather more intricate than is often imagined, and prove more and more how well founded is the very reasonable rejection of the doctrine assigning symptoms to mere strangulation of only omentum. It has occurred to me while writing that some might think that a portion of intestine was possibly here reduced in the manipulations. This is not possible; we were keenly on the look out for any such fact, which would have been welcomed, and could not under the circumstances have eluded observation. No change whatever in the bulk of the hernia resulted until it was tapped. A similar case is recorded by Mr. Thomas at the end of his work on intestinal obstruction, but the above is the first that I have myself recognised. Pray excuse the length to which I have gone.

I am, Sir, yours truly,

Rodney-street, Liverpool, April 6th, 1885. RUSHTON PARKER.

"SMALL-POX AND VACCINATION."

To the Editor of THE LANCET.

SIR,—In your last week's notes in Parliament, at p. 643, it is not made clear that the seventy-eight persons engaged at the London small-pox hospitals, about 7 per cent. of the whole number employed, who had had small-pox had it before they were engaged at those hospitals. When Mr. G. Russell from his official position had to state that his department had no reason to doubt that "none of the nurses at any of the London small-pox hospitals who had been *duly vaccinated before entering on their duties* have ever caught small-pox" is substantially accurate, he goes on to say that this might have been more guardedly expressed in "Facts concerning Vaccination." The words now put in italics show how sufficiently the expression is guarded, and most members of the Local Government Board would probably admit this.

Of late it has been common to report cases of small-pox after vaccination, not only when the vaccination was performed after the reception of small-pox infection, but also where there is no evidence of any effect of revaccination having been produced. In times of great pressure persons have been engaged for duty at small-pox hospitals before their revaccination was known to be effective. Even

a previous attack of small-pox is not a positive safeguard unless tested by a revaccination. All the evidence accumulated to the present time conclusively proves that vaccination has lost none of its protective power, and we are constantly reminded to our cost that small-pox has lost none of its virulence.

I am, Sir, your obedient servant,

April 4th, 1885. WILLIAM SQUIRE, M.D., F.R.C.P.

DONBAVAN *v.* MORRISON.

To the Editor of THE LANCET.

SIR,—The above case came on for trial before the judge of the county court, Croydon, on the 31st ult. After all the points on which we relied had been ably put forward I regret to state that the judge, without calling on the defendant's counsel for reply, gave judgment in his favour, giving costs also on the higher scale, alleging as the grounds for his decision that he held that a workhouse and workhouse infirmary were public institutions within the meaning of the 5th section of the Coroners' Witnesses Act, and that the officers of such institutions were not entitled to payment for making post-mortems and attending and giving evidence; thereupon our solicitor applied for leave to appeal, which the judge, after some hesitation, assented to.

This decision, if not upset on appeal, will seriously affect the interests of all workhouse medical officers, who in future will not be paid for such examinations and evidence, and it practically reverses the system that has been followed since the Act came into force, which has been to pay workhouse medical officers for such examinations and evidence.

The trial so far will cause a heavy drain on the very limited income of our Association, and without immediate pecuniary assistance it will be impossible for us to prosecute further proceedings. May I ask, therefore, my professional brethren who are able and willing to at once announce their intention of supporting us by forwarding subscriptions to me. I am, Sir, yours obediently,

JOSEPH ROGERS,
Chairman of Council, Poor-law Medical Officers' Association.

31, Montague-place, W.C., April 1st, 1885.

"ALLEGED DEATH FROM VACCINATION."

To the Editor of THE LANCET.

SIR,—After reading your article I feel it due to myself, being misunderstood, to say:—1. That I accept, and have for twenty years accepted, the proposition that vaccination modifies small-pox. 2. I do not consider "arm-to-arm vaccination an undesirable method of procedure," except in the case of tuberculous infants. 3. I was called urgently, for the first time, on the 14th ult., to the deceased infant, H. J. Downing Walker, because the child was "in a fit." The difficulty in breathing spoken of in Court by Mrs. Walker was on the 12th ult. Any observations made in Court as to the effect of point vaccination as compared with arm-to-arm vaccination were given only as the result of my own individual experience. Finally, in the certificate, which the superior wisdom of a coroner's jury was pleased to condemn, it was my intention to state, according to my light, the prominent medical facts preceding death, and that being so, the certificate, when written, was a "correct statement" of the opinion of

Your obedient servant,

Regent's-park, N.W., April 6th, 1885. C. C. WHITEFOORD.

AN EASY METHOD OF CURE FOR SALIVARY FISTULA.

To the Editor of THE LANCET.

SIR,—The following method does not appear to be mentioned in any of the usual text-books of surgery:—

J. K——, a fish salesman, came to me about the New Year with a fistula of the parotid duct resulting from a former knife wound. The flow of saliva was continuous, but was much aggravated at meals, and when opening oysters in the course of his business. Applications of nitrate of silver, pure nitric acid and a hot wire were tried without success, as all communication with the mouth seemed shut off. On Jan. 20th two needles threaded on one fairly strong piece of silk were successively passed through the fistula into the mouth on a rather lower level than the external fistulous orifice, piercing the buccal mucous membrane about a quarter of an inch apart. The needles were then removed, and the threads firmly tied and cut off short, thus leaving a ligature enclosing part of the internal wall of the duct, a portion of mucous membrane, and the intervening structures, but in no way preventing the healing of the external wound, as would be done by the seton usually recommended. The edges of the fistula were touched with pure nitric acid on Jan. 22nd, and some swelling of the side of the face ensued. On Jan. 25th a scab had formed outside, and nearly all the saliva found its way into the mouth. This scab came off a few days later, leaving the skin soundly healed, and the ligature inside cut its way through the mucous membrane on Feb. 11th, since which time the man has experienced nothing differing from the normal condition.

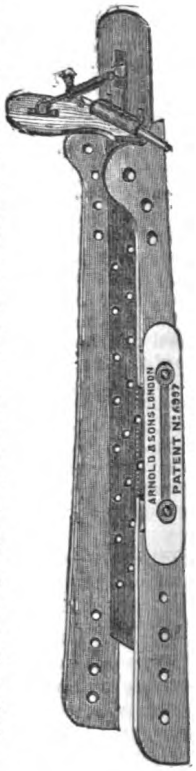
I am, Sir, yours faithfully,

Rochdale, April 6th, 1885. ALFRED HODGSON, M.B. Aber.

IMPROVED FRACTURE BOX.

To the Editor of THE LANCET.

SIR,—I wish to bring under your notice a new invention, which I presume will be of great advantage to surgeons in the treatment of fractures of the leg. It is an improved fracture box, suitable for any fracture of the leg, simple or compound, or disease of the ankle-joint requiring rest in position. It consists of three pieces: bottom and two sides. The bottom is pierced with drainage holes, and has a hinged foot-plate attached. This foot-plate is further connected to the foot end of the bottom splint by a regulating screw. This screw is a "fine thread" screwed socket rotating on a screwed pin. This screw regulates the angle at which the foot-plate is required to be kept. One of the side splints is plain; the other is in two parts, kept together by a brass slide having a longitudinal slot of the diameter of the thumb-screws, on which it runs, and which serve to retain it in position. This is the "interrupted" splint of the fracture box. It can be made a plain splint if required, or can be fixed at any divergence by the thumb-screws. One of these interrupted splints is only required, as both side splints are reversible, and will fit either side of the apparatus. The usual straps and buckles tie it together. The accompanying woodcut will assist in giving a clear idea of the nature and construction of the apparatus.



I remain, Sir, yours sincerely,

JAMES J. FOLEY,
Riversdale, Midleton, co. Cork, April, 1885. Medical Officer, Midleton Hospital.

NEW WORKHOUSE INFIRMARY AT WEST BROMWICH.—The *Building News* gives a lithograph of the New Infirmary, West Bromwich. Accommodation is provided for 224 patients. The arrangement of the wards is on the pavilion system. The contagious and infectious wards are separated from the buildings, and so arranged that each ward may be isolated. None of the buildings exceed two storeys. The staircases are of stone, and numerous hydrants have been placed in convenient positions. The cost of the infirmary has been about £12,500.

WITH THE TROOPS IN THE SOUDAN.

(From our Special Correspondent.)

Base Hospital, Camp near Suakim, March 23rd, 1885.

FOOTSORE, dust-begrimed, and desperately tired, I sit down to write you a few lines from this entrenched spot, as I feel assured any information from the front, however brief, will be welcome from this newly selected battle-field of the African Soudan. Scarcely had I arrived in this port ere private news reached me of a projected advance of our troops in the direction of Tamai, *en route* for Berber. I at once proceeded on foot under a blazing sun to the head-quarters of our camp, situate about a mile from the Arab town, and sought an interview with General Graham, now in command of the troops out here. On inspecting my papers, however (your certificate of appointment as "special" I refer to), he remarked that my credentials were not exactly in order, and explained to me that a properly attested registration certificate should have been obtained from the proper authorities at the Horse Guards, in order to place me on the same footing as other specials accompanying the troops in the field. I explained how hurried my departure had been from England, and after a few minutes' conversation the difficulty seemed to be bridged over, and a very pleasant interview terminated in the Chief of the Staff pointing out the principal medical officer's tent, and referring me to that gentleman for any future instructions for my guidance on the subject. Surgeon-General Barnett at once received me in a most cordial manner, expressed his pleasure at meeting a representative of THE LANCET, and assured me that no obstacle whatever would be placed in my way, but every facility possible afforded for my obtaining any medical or surgical records of such cases as I thought fit to notice, and were likely to interest the profession at large, at the same time handing me a paper (a general order) for my perusal, whereby I was enabled at a glance to ascertain that a very careful disposal of the medical staff had already been made in view of the troops moving westward to confront and give battle to the enemy in the plain.

On Thursday morning last, March 19th, I was aroused at 3 A.M. Hurriedly dressing, partaking of biscuit and a good cup of strong coffee, and then filling my small handbag with a tourniquet, some artery forceps, surgical needles, silk, and such other necessaries likely to be useful, as well as comforting in case of accident or delay on the road, I quitted the easy quarters on board the steamship *Arab*, and proceeded on shore in company with a "special" bent on a representative errand as myself. On arriving at headquarters, we found the column had left the camp about an hour before our arrival, and not being able to secure a horse for myself, I had to part company with my companion and follow General Graham's force to Asheen on foot and alone—a by no means happy prospect, in view of a some seven or eight miles' dusty walk over a sandy desert under the scorching rays of a tropical sun, and in the presence of a subtle, active, and relentless foe. By the time the sun had risen, a light, cool, northerly breeze had sprung up, so that my solitary tramp turned out not quite so unpleasant a one as I expected it would have been. Doing my level best, as they say—some five miles an hour,—I came up with the rearmost of the camel train, in charge of native Indian drivers, and in an hour afterwards I had forged so far ahead that I could easily discern the entire distribution of the force in front, and in two hours from the time of leaving the ship was up with and coming on at a canter with the Brigade of Guards, and felt not much the worse for my long walk. Soon afterwards a halt in front, and an order from the General for the camels and mules to immediately come into square, suggested the probability of a "find," either for refreshment or foe. "Breakfast, I guess," says a sturdy mule-driver close to me, the wish on his part being father to the thought, as our stomachs were by this time empty enough. Not long, however, had we to wait for a decision on this point. An extended line of white-greyish smoke making its appearance over the helmets of the men standing in front of us, and the sharp rattle of musketry heard on our left front face told no uncertain tale, but proclaimed the fact that the enemy were there—more than that, not at bay, but, as their usual custom and valour is, were charging right up to our very front. Cavalry, with their gaily decorated lances, were seen dashing along in one direction, whilst our Guards, the 49th, 53rd, and 70th, were doing their very best pegging away in another. The din of battle proceeded, whilst dust and smoke soon obscured from view nearly everything going on around us. After quitting the camel convoy I had marched on with the Guards, and then joined the hospital and bearer company, hoping to see what wounded were brought in from our front face of the square; but in the hurry and scurry, the confusion and rapidity of movements going on around me, I for a time lost touch of the medical department, and, by getting out of the way of a score or so of refractory camels, suddenly discovered myself outside of the square that had fortunately, and yet quickly, been formed at the base of a small hill to resist the onslaught of a most brave, active, and determined enemy. For some seconds I was at a loss to know what to do. There I stood alone, unattached, and withal perfectly unarmed. I felt for at least once in my life that I had outstepped the bounds of discretion, and had really no business where I was, and further than that, if I remained much longer just at that particular spot looking at the action, and admiring the pluck as well as the dash of our own brave fellows in mounting the spur of the hillock, and carrying up planks and bags to form a zereba, the occasional thinning of the dust cloud and blowing away of the smoke giving me an opportunity now and then of getting a glimpse of what was going on in this tug of war, I myself would be as near as possible in a line betwixt two fires, and form an admirable target for either side which should choose to fire upon me. I was in a dilemma, it is true, having to determine upon one of two dangerous alternatives—either to dash back through the dust and smoke and try to regain the inside of the Guards' square, with the prospect of being mistaken and shot at as an enemy, or make for some safe distance in the rear. Acting on a natural instinct, impulse if you will, and which has stood my friend on many a trying occasion before, I decided for the latter, and at noon exactly started across the plain for Suakim, and the entrenched camp some seven miles away. Two young men, who had come out with the force in the morning, joined me a few minutes afterwards, and I at once felt relieved by their companionship in this retrograde movement on our parts; however, they, like myself, were amateurs, and had come out of camp—just as Easter Monday holiday folk do on Brighton Downs to see what was going on; and one of them had in his possession a large, ugly revolver, which he persisted in carrying in his hand at full cock. As I considered there might possibly be, from inexperience in its use on his part, more danger in this friend than in a foe, it was with no small degree of relief to my feelings that we three parted company, having reached a place of comparative safety about four miles away from the action that was then going on. By 2 P.M. I was inside the West Redoubt, the furthest post out held by the English in the plain, and learnt from the officer in charge, Lieut. the Hon. H. White of the Guards, the great danger I had run in going out, and especially in coming in unarmed over a wide plain that might then actually be in possession of the enemy, who give no quarter, but slaughter every man and beast they meet. From the crow's nest of this redoubt we watched the fight going on; saw that the brave British force had already secured the low hills which dominated the wells; but had formed a zereba as well as established heliographic communication between head-quarters and themselves. By three o'clock the fight was practically over. The gallant 70th were left to hold the zereba, and the remainder of the expeditionary force returned to camp to give the men a good meal, and get a little rest in their entrenched position after a most fatiguing march out, and the gallant exploits of the day.

Poor Lieutenant Dalliston, of the Guards, fell early in the day, shot dead, and very soon afterwards Surgeon Lane, also of the Guards, as gallant a fellow as ever breathed, and as accomplished a young surgeon as ever graced the pages of the Army List, sank to earth pierced by a bullet wound through his left lung. He was very carefully brought back to camp; considerable hæmorrhage meanwhile ensued, and all felt that his wound was desperately dangerous. The following morning he was dying, no possible hopes whatever being entertained that he could live out the day. He breathed his last about two o'clock in the afternoon. Every care and attention was paid him by his medical brethren, but all to no purpose. He passed away in the prime of life and pride of manhood, to give place for others to emulate

him in quality and action, as well as to place another lasting testimony on the record of fame that there are men in the non-combatant as well as the combatant branch who are prepared to lay down even their lives, if needs be, in the execution of their duty for their Queen and their country. I had telegraphed to you early in the day of the serious character of his wounds, as well as that of some other officers; but from some misunderstanding on the part of the telegraphic company, all messages now being under a military censorship prior to being sent away, my report, containing ciphers to save expense, was stopped, and handed back to me in consequence.

Our list of casualties in this slight action, and the day day following, when a relieving column was despatched to the zereba, was heavy enough. Sergeant-Major Nicholls was stabbed to death, and some men of the 2nd Scots, 1st Coldstream, and 2nd Grenadier Guards fell mortally wounded by Remington bullets. Major Robertson, of the Bengal Cavalry, was stabbed by a spear very severely. Major Harvey, of the 5th Lancers, received a bad thrust through his left thigh, but is doing well. Most of the wounds were gunshot ones, the rebels not getting within thirty yards of our squares. The injuries inflicted by spear thrusts are simple clean flesh-cuts, the enemy's weapon having a razor-like edge. These wounds under ordinary antiseptic dressing do well, and generally heal by first intention. Their large double-edged sword, used with great force, held in the two hands, and generally aimed at the neck and head, produces most ghastly wounds, severing flesh, vessels, and bones in the course of its descent, and killing its victim outright. No man unhorsed in fight ever escapes the fury of these ruffians, nor lives to tell the tale of a hand-to-hand encounter with their active and brave but relentless, foes. (*Vide* sketch.)

Corpse of a private after falling into the hands of the enemy. One sword-wound in the neck, severing everything through the cervical vertebræ; the rest are spear-wounds on the chest and arm, six in number. (Sketched at Base Hospital, March 23rd, 1885.)

Saturday (21st) was a quiet day as far as the home force was concerned; but much firing was heard in the direction of the Hasheen zereba, although no reports had come in from them until Sunday, the 22nd.

On Sunday (22nd) a large force left the camp before daylight, taking a southerly direction towards Tamai, twelve miles distant. Five or six miles out, the camp, whilst the men were building a zereba, was surprised by a large number of the enemy, and a regular stampede among the camels and camp followers in consequence ensued. The details of this affair must sooner or later reach England, and some explanation will be required to account for the sad loss of life that has taken place amongst the troops and men employed. As I write this an order has reached the Base Hospital from headquarters for the medical staff to be in readiness to receive a large number of wounded from the field. A large and powerful escort has gone out to bring the wounded in. During the whole of this day (Monday, 23rd) Brigade-Surgeon Hinde, assisted by his energetic staff at the redoubt, have been working hard to have everything in readiness to receive them. About 100 are expected. In this camp Surgeon-Major Tanner can accommodate 70 in beds, 20 can be taken in the Auxiliary Hospital at Quarantine Island, whilst 55 could be removed on board the *Ganges*.

The hospital tents are both roomy and airy, being lined with double protective covering overhead, and are square, not bell-shaped, as wrongly described by some correspondent. The operating tent, under the superintendence of Surgeon-Major Tobin, is a picture of comfort, method, and order, and reflects much credit on the indefatigable officer in charge of it.

7 P.M.—Just dusk, and the wounded are being brought in. Poor fellows, I pity them indeed! Their faces, and those of the gallant band who have brought them, are so brown and covered with dust that they are scarcely recognisable; but never mind—comforts, in the shape of a nice bed, good warm soup, hot tea, or even brandy-and-water, await each one, as the necessity of his case demands it. The dressings, moreover, are so carefully adjusted, and the patients seem to have had such good attention in the field, that they will enjoy the comfort of a quiet night before their wounds are further inquired into.

LIVERPOOL.

(*From our own Correspondent.*)

MEDICAL FACULTY, UNIVERSITY COLLEGE.

THE vacancy caused by the resignation of Dr. Ewing Whittle, of the chair of Medical Jurisprudence and Public Hygiene, has been filled by the election of Mr. Frank T. Paul, surgeon to the Royal Southern Hospital, and surgical tutor in University College. Mr. Paul possesses eminent qualifications for the chair, having been a pupil of the late Dr. Alfred Swayne Taylor at Guy's Hospital, and having also held the appointment of pathologist to the Liverpool Royal Infirmary, where he was previously resident medical officer for nearly three years. He has personally made upwards of 1000 post-mortem examinations, and was for some time demonstrator of physiology. Altogether, the appointment is one on which the College may be congratulated.

THE LOCK HOSPITAL: COMPARATIVE RARITY OF SYPHILITIC IRITIS.

At a recent meeting of the Medical Institution, Dr. Bernard, surgeon to the Lock Hospital, read a paper on "The Treatment of Constitutional Syphilis," in which he remarked on the rarity of cases of syphilitic iritis seen in the hospital. The total number of patients treated averages over 600 annually, of whom the larger proportion are suffering from constitutional syphilis. Mr. Shears, senior assistant-surgeon to the Eye and Ear Infirmary, who took part in the subsequent discussion, observed that syphilitic iritis was very frequent among the out-patients of that institution. Subsequent inquiries showed that in a period of ten years (May, 1875, to March, 1885) there had been only seventeen cases observed in the Lock Hospital, and in the majority of these the eye is affected either on admission or very shortly afterwards. A very probable explanation is that the cases seen at the Eye and Ear Infirmary are those of patients who have neglected the primary disease, the influence of mercurial treatment in both preventing and curing syphilitic diseases of the eye in particular, being now undisputed.

STREET NOISES.

For some years past most of our leading thoroughfares have become insufferably noisy, there being an incessant roar of traffic from a very early hour in the morning until very late at night. The wood pavement does not appear to find much favour with the local authorities, who have only permitted a very limited use of it in the neighbourhood of the Northern Hospital, in Bold-street and part of Church-street, thoroughfares devoted to fashion. The asphalte pavement deadens the sound somewhat, though it has the disadvantage of being very dusty. Medical practitioners, who are obliged to live in or near leading thoroughfares, suffer much from this annoyance, as also from much noise

which might be avoided, such as street music and singing, newsvendors' cries, &c. A recent local Act, which does not appear to be generally known (Liverpool Improvement Act, 1883), contains a section (29) which requires every street musician or singer to depart from the neighbourhood and from within hearing of any householders on being requested to do so by the latter, or any member of his family, or servant, or by any constable. A refusal to comply with this perfectly reasonable request renders the offender liable to a penalty of 40*s*.

CITY CHURCHYARDS.

This city contains within its corporate boundaries a large number of intra-mural churchyards and cemeteries which, since the year 1854, have been closed absolutely against all interments. Their appearance, until very recently, has been dismal in the extreme, presenting a dreary outlook of neglected graves and tombstones, while some have been made the receptacle for all the refuse of the adjoining street. Some years ago the incumbent of St. James's Church, Toxteth-park, the churchyard of which was in a most disgraceful condition, took steps to improve it, including the planting of trees. The experiment has proved both successful and contagious, other churchyards and cemeteries having been planted with trees and made into recreation-grounds. Another churchyard, St. Luke's, is now being laid out; and it is probable that in the course of years every intra-mural burial-ground will have been similarly transformed. This will conduce greatly to the health and comfort of the inhabitants in their neighbourhood.

THE ROYAL SOUTHERN HOSPITAL.

At the Royal Southern Hospital there are several cases of operation for the removal of new growths, under the care of Mr. Paul. A recurrent melanotic sarcoma of the neck, primary in a submaxillary gland, is worthy of note. The original growth was removed two years ago from a man aged forty-eight; he has since been in good health, but the recurrence was very extensive and deep, so that, although the wound is healing well, the ultimate prospect is not encouraging. Among the most interesting are two cases of carcinoma of the antrum, involving removal of the whole of the upper jaw and contents of the orbit. Mr. Paul refers to six cases of this nature which he has recently met with, all of them presenting the same clinical history, and one which enables the diagnosis from sarcoma to be made without reference to the microscope. In all, the first symptom noticed by the patient was a formation high up in the nostril on one side, which easily bled and gave rise usually to some unpleasant discharge; subsequently, at the inner angle of the orbit, a small soft tumour grew, displacing the eye, and this was the immediate cause of the patient's applying for admission to hospital. In no case was the antrum distended, as in sarcoma. The growth evidently began in the mucous membrane of the antrum, fungated into the nostril, and then spread up, probably along the nasal duct, to the inner angle of the orbit. Microscopically, two of the cases were of the ordinary squamous epithelioma, and the remaining four the normal cylindrical-celled carcinoma of this part. Both the patients have recovered temporarily from this extensive operation, but one already has a recurrence. An epithelioma of the back is another case not very common; and two old cases, come up to show themselves in good health, were encouraging—one, an excision of the rectum for cylindrical epithelioma nearly four years ago, still free; the other, a colotomy for the same growth in the sigmoid flexure of the colon six months ago. Mr. Paul has two cases of compound fracture of the leg into the ankle-joint, in which very good results have been obtained by treatment with his splint and wiring the bones; and two or three cases of talipes, in his splints, undergoing a gradual improvement.

NORTHERN COUNTIES NOTES.

(From our own Correspondent.)

HEALTH LECTURES AT MORPETH.

A COURSE of six lectures of a popular nature has been commenced at Morpeth, and it is satisfactory to know that the public have taken a considerable interest in the matter, as evinced by an attendance which is said to have fully tested the capacity of the Town Hall. A few years ago a popular lecture by one of our professional brethren was a rare event in the North, and only "the leading men" ventured to address the public, and then on non-professional subjects as a rule. Now the younger members come forth, to the great advantage of the public, who desire, and will have, medical information and light on sanitary subjects. The first lecture was by Dr. David Drummond of Newcastle, and his subject, "House Sanitation," was ably treated, dwelling with force and lucidity on the importance of ventilation and drainage, and giving a number of very striking illustrations of how such diseases as scarlet and typhus fevers and consumption were generated by neglect of the principles laid down. The second lecture was given by Dr. Byrom Bramwell of Edinburgh (whom we claim here as a Tynesider); his subject, "Common Diseases, their Cause and Prevention," was very ably treated, and the Hall, if possible, was more crowded than on the former occasion. It is as well to mention, as bearing on the success of these sanitary lectures, that the experiment was tried, which has proved so successful, of charging one penny for admission to each lecture. This has been shown to be a better plan than free admission; for what people get for *nothing* they generally attach little or no value to.

THE CHLORAL HABIT.

A very distressing case has occurred in Durham City since my last letter. A lady, the wife of a prominent citizen, was found dead in her bed. It was stated at the inquest that she suffered from sleeplessness, for which she was in the habit of taking chloral without medical advice, and it was shown that death had taken place "from syncope, accelerated by chloral, self-administered."

AN EXAMPLE FOR TRAVELLERS IN SUNNY LANDS.

Sir George Elliott, Bart., M.P., has sent large boxes of beautiful flowers from the south of France to Durham County Hospital, Sunderland Infirmary, and Newcastle Infirmary, with instructions that they should be dispersed amongst the sick wards. Sir George has frequently shown his sympathy with the sick poor of the north before, but I venture to say this last act of his will be felt by them as most graceful and considerate.

MEASLES AND RÖTHELN IN THE NORTH.

There is now rather a smart epidemic of measles prevalent at Gateshead. I have heard of as many as forty pupils in one school being absent from this cause. Several adults have been attacked, and, as usually observed, have suffered more severely than children. Some cases have been evidently of the character of rötheln; but as a rule the epidemic has not shown the severity nor the fatality of the Sunderland outbreak, which, I regret to say, still prevails in a bad form in that borough.

TRIPLETS IN THE NORTH.

Since the New Year set in several cases of triple births have occurred in the north, both sides of the Tyne having received augmentation to their population in this way, and also some of the mining districts of Northumberland. If we suppose that the usual midwifery statistics are correct as showing triple births to take place once to every 6000 cases, we must allow that the experience of Mr. John Foggin, a young surgeon in practice here, has been quite unusual, for many practitioners will not have a case of triplets in a lifetime, while Mr. Foggin has had a case on January 8th last, two boys and a girl born alive; and again on March 28th, three boys born alive, and still living. I believe Mr. Foggin has been successful in obtaining the Royal Bounty for the first case, and is also hopeful of getting it for the last; both have occurred in the wives of poor and industrious people.

Newcastle-on-Tyne, April 6th.

PARIS.

(From our Paris Correspondent.)

THE SUSPECTED ARSENICAL POISONING CASE.

IN my letter of Jan. 31st I gave an account of a suspected case of poisoning by arsenic. The supposed criminal, whose name is Pel, and a clockmaker by trade, is soon to appear before the Court of Assizes of the Seine. The trial promises to be most interesting, and at the same

time most perplexing, as the preliminary examination has been before the magistrates and medical jurists. Owing to the mysterious disappearance of the maid-servant of the accused man, a stove in which he is strongly suspected of having burnt the body of his victim, or perhaps victims, was seized; but as the dimensions appeared somewhat too small for the execution of his purpose, the medical experts had one made exactly like it, and by way of experiment burnt the corpse of a human adult in it. They were greatly surprised at the rapidity and completeness with which the body (previously cut up) was consumed. In fact, it might be used as a crematory. That belonging to the accused, which was rather primitive and unique of its kind, is supposed to have been devised by himself, and has been carefully preserved in the same condition as when found, as it will necessarily be brought forth as evidence against him. Although very small, yet the mouth of the stove was found large enough to admit a man's head, entire. It has also been noted that Pel followed very assiduously, and for a long time, the course of Medical Jurisprudence delivered by Professor Brouardel at the Morgue. Another crushing circumstance against the accused is that when the examining magistrate observed to him that arsenic was found in the body of his first wife, which was exhumed, he replied that that was not astonishing, as she had been treated for two years with arsenic; but it has been ascertained that none of the medical men who attended her had prescribed that substance, nor did any of the prescriptions made up at the pharmacies for her contain it.

REMOVAL OF A CANCEROUS KIDNEY.

Dr. Péan, one of the most daring French surgeons of the day, and a well-known ovariotomist, submitted to the Academy of Medicine last week the case of a patient (an English lady) from whom he had removed a cancerous kidney about fourteen months ago. Dr. Péan had seen the patient six years previously, but he did not then consider the case ready for any operative measure. She had in the interim consulted some of the most eminent surgeons in London, who declared, in response to her desire for an operation, that it was impracticable. She then came to Paris to consult Dr. Péan again, and when he saw her about fourteen months ago, he found her in the last stage of marasmus, and the tumour occupied as much of the abdomen as would a nine months' gravid uterus. The removal of the tumour was decided upon by gastrotomy, and the operation was effected by making an incision through the abdominal walls, along the linea alba from the pubes up to the epigastric region. The tumour was removed with some difficulty, and was found to weigh six kilogrammes, or about thirteen pounds, and the whole operation occupied a little more than an hour. It is, however, a pity that Dr. Péan did not mention whether the operation was performed under the influence of chloroform or other anæsthetic, or whether antiseptics were employed or not. Professor Charles Robin, who examined the tumour histologically, pronounced it to be an epithelioma of the kidney. Dr. Péan stated that, although the operation was performed about fourteen months ago, he did not then wish to submit the case to the Academy, as he was afraid of an early relapse. This, however, has not occurred; the general state of the patient has never failed to improve from the commencement, and the remaining kidney has been found sufficient to produce the normal quantity of urine. The urine of the patient was lately examined by M. Méhu, an eminent chemist, who declared that it was of the same chemical and histological constitution as that of women in health.

THE HEALTH OF THE ARCHBISHOP OF PARIS.

The Archbishop of Paris, who was reported to be suffering from bronchial catarrh, is now officially pronounced by his medical attendant to be out of danger, and notwithstanding his advanced age (his Eminence being an octogenarian), every hope is entertained of his recovery.

Paris, April 7th.

ANONYMOUS letters containing threats to blow up Netley Hospital with dynamite have recently been received by the Commandant and other officials of that institution. A few nights ago a package, which was immediately destroyed, was found in the vicinity of the hospital, and since then increased vigilance has been shown, and the force of military police stationed at the hospital has been increased.

THE ROYAL COLLEGE OF SURGEONS.

AT a quarterly meeting of the Council, held on Thursday last, the minutes of the last meeting were confirmed.

The thanks of the Council were given to Mrs. Fairlie Clarke for the presentation of drawings, &c., illustrating Diseases of the Tongue, which had been prepared by her late husband.

No essay was received for the Jacksonian Prize. The subject for next year is to be the Pathology, Diagnosis, and Surgical Treatment of Diseases of the Thyroid Gland.

Mr. E. H. Fenwick, of the London Hospital, was elected an Examiner in Physiology under the combined scheme.

The Committee of Charters and Bye-laws presented their report, the reproduction of which we must defer till next week. It was agreed that the Association of Fellows and Members be informed that the College is about to proceed to get the necessary charters and bye-laws drawn up.

The question of recognition by the College of the vaccination certificates granted at Belfast, having been again raised by a letter from Professor Redfern, was referred to a select committee.

A request from the Western University, London, Ontario, to have its teaching recognised, was referred to a committee of management of the two Colleges.

Mr. Durham gave notice of the following motion, to be brought forward at the next meeting of the Council: "That seven delegates from this College be appointed, with authority to invite an equal number of delegates from the Royal College of Physicians, to meet and confer upon what steps, if any, can be taken to enable the two Colleges to obtain the legal right of giving the title of Doctor to persons who shall have obtained the licence of the Royal College of Physicians of London, and the diploma of Member of the Royal College of Surgeons of England."

MAHOMED MEMORIAL FUND.

THE following additional subscriptions have been received:—

	£	s.	d.
Dr. Edward Chisholme (Sydney)	5	0	0
Dr. Arthur Evershed ...	1	1	0
H. Lund, Esq.	1	1	0
Albert Martin, Esq., M.B.	5	0	0
T. D. Ransford, Esq. ...	1	1	0
A. H. Tubby, Esq.	2	2	0

A meeting of the General Committee will be held in the Governors' Court-room, Guy's Hospital, on Thursday, April 16th, at 4.30 P.M., to receive the report of the Executive Subcommittee, and to consider how best to make use of the fund.

ARTHUR E. DURHAM, Treasurer.
JAMES F. GOODHART, W. H. A. JACOBSON, } Secretaries.

COUNTY COURT, CROYDON.

MEDICAL FEES FOR NECROPSIES IN WORKHOUSES.

In re DONBAVAN *v.* MORRISON.

MR. W. J. FRASER, who appeared for the plaintiff, having stated the facts, contended that it formed no part of the duty of the medical officer of the Croydon Workhouse and Infirmary to make a post-mortem examination of the deceased's body. The case was properly reported to the coroner's officer, who, having deemed an inquiry necessary after consulting the coroner, the medical officer not being certain as to the actual cause of death, was ordered by the coroner to make a post-mortem. It was no part of such medical officer's duty to make such examination at the coroner's request. He was not remunerated for it. Indeed, prior to the appointment of the present (recently elected) coroner, his predecessor, Mr. Carter, had for years paid the fee. The workhouse and infirmary were not public institutions within the meaning of the Act. They were exclusively maintained at the expense of the ratepayers of the union, and were for destitute persons and none others. Unless a person was destitute, or in fact a pauper, there was no right whatever on the part of such person to receive treatment

therein. No person could be treated in a workhouse infirmary without becoming a pauper. The plaintiff was therefore the medical officer of a pauper, and not of a public, institution. A coroner had no more right to call upon the medical officer of a workhouse to make a post-mortem without paying the stipulated fee than he had to require the ordinary medical practitioner to do so, who might have been casually called in to attend upon a person upon whose body an inquest had to be held, and also a post-mortem. A public hospital or infirmary was an institution open for the reception of any person, no matter what might be his or her rank in society who sought its aid and could be cured therein. The word "public" was general in its application, and applied to all classes of persons, whereas a workhouse and infirmary was only for the pauper and no other. The word "public" meant public generally, and not any section such as the destitute and the pauper. In conclusion, Mr. Fraser saw that, whether the object for which the statute was passed, the mischief at which was aimed, the plain and natural interpretation of the language used, or the fact that workhouses were not mentioned or even referred to, was regarded, no other conclusion could be come to other than that the plaintiff was entitled to his fee, and it would be a manifest injustice to compel him to go without it, and to give that to him would be in accordance with the practice which had for the most part prevailed since the passing of the Act in 1841, and in harmony with the opinion of the Poor-law Board (now the Local Government Board), which was by no means an unworthy authority.

The judge, Mr. Lushington, gave a verdict for the defendant, with costs on the higher scale, alleging as the grounds for his decision that a workhouse infirmary was a public institution within the meaning of the section.

Mr. Fraser thereupon applied for a case for appeal, which the judge assented to.

Obituary.

JAMES WHITEHEAD, M.D., F.R.C.S.

WE regret to record the death on the 3rd inst., at Sutton, Surrey, from cancer of the œsophagus, of Dr. James Whitehead, late of Manchester, in the seventy-fourth year of his age. The deceased, who was a native of Oldham, obtained his professional education at Manchester, Westminster Hospital, and Paris. In 1845 he obtained the diploma of Fellow of the Royal College of Surgeons of England, in 1850 the degree of M.D. from the University of St. Andrews, and was elected a Member of the Royal College of Physicians of London in 1859. He was also a member of various British and foreign scientific societies. Previous to its union with Owens College, Dr. Whitehead was lecturer on Obstetrics at the Royal School of Medicine, Manchester, and some years ago held the position of senior officer in ordinary at St. Mary's Hospital, and also that of Demonstrator of Anatomy. Amongst his published works are: "Diseases of the Uterine System," "Hereditary Diseases," "The Wife's Domain," "The Rate of Mortality in Manchester," and "Reports of the Manchester Clinical Hospital;" he also contributed various papers to the medical journals. In conjunction with the late Dr. A. Schoeff-Merei, Dr. Whitehead was a founder of the Manchester Clinical Hospital.

THOMAS HOWKINS, M.R.C.S.

MR. THOMAS HOWKINS died of heart disease at Torquay, in the fifty-fourth year of his age, on the 29th ult. His career as a medical student at University College, London, was a distinguished one. He gained, amongst other honours, the gold medal in Professor Erichsen's class of surgery; and, after obtaining the membership of the Royal College of Surgeons, established himself as a dental surgeon in Birmingham. Here he soon rose to leading practice, was appointed dental surgeon to the Children's Hospital, and more recently lecturer on Dental Physiology and Surgery at the Queen's College. For some years Mr. Howkins was one of the members of the Council of the latter institution; and when the local practitioners of dental surgery formed a Society for their specialty, Mr. Howkins was called to the presidential chair. His opening address was characteristic of him, as an accomplished surgeon and an eloquent speaker. He held one of the highest positions, as a philanthropic worker, in the Masonic brotherhood, and is sincerely mourned in a wide circle of devoted relatives and friends.

Medical News.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on the 2nd inst.:—

Burd, George Frederick, St. Bartholomew's Hospital.
Rowlands, Thomas Frederic Watkin, Guy's Hospital.
Whitwell, Alfred Frank, St. Bartholomew's Hospital.

DR. E. B. TRUMAN has resigned his office as public analyst to the borough of Nottingham.

THE eminent zoologist, Karl Theodore Ernest von Siebold, Professor at the Munich University, has just died at Munich.

MEDICAL MAGISTRATE.—Dr. Henry G. Thompson has been appointed a Justice of the Peace for the borough of Croydon.

VACCINATION GRANT.—Mr. W. Hood, of Castlegate, York, has received the Government grant for successful vaccination (third time).

ON the 31st ult., the foundation-stone of the new sanatorium for Hull, now in course of erection, was laid by Dr. King, Sheriff of the town.

THE Prince of Wales has consented to preside at a dinner in aid of the funds of the North London or University College Hospital, on May 13th.

AN additional ward to the Birkenhead Corporation Fever Hospital was opened on the 31st ult. The erection has involved an expenditure of about £600.

IT is stated that the first report of the Royal Commission on the Housing of the Working Classes has been agreed to, and that it is now in the hands of the Government printers.

THE SHOEBURYNESS DISASTER.—A testimonial is to be presented to Mrs. Long, of the Prittlewell Sick Nursing Fund, upon whom rested the burden of nursing the sufferers from the late disaster at Shoeburyness.

ROYAL COLLEGE OF SURGEONS OF ENGLAND—At a meeting of the Council on the 9th inst., Mr. Edwin Hurry Fenwick, F.R.C.S. Eng., Assistant-Surgeon to the London Hospital, was elected Examiner in Elementary Physiology.

ARRANGEMENTS have been completed for a "Conference on Education under Healthy Conditions," which is to be held in Manchester from April 14th to the 17th inclusive. The conference will be under the presidency of Lord Aberdare.

PARKES MUSEUM.—A lecture was delivered in this institution on the 26th ult. by Mr. Fletcher, of Warrington, entitled "Smokeless Houses and Manufactories." The lecture was followed by a discussion, in which Dr. Coffin, Mr. Coles, and others took part.

IN reference to the present movement to enlarge the Royal Surrey County Hospital, it has been suggested that the children's ward of the new wing might be specially termed the "Gordon Ward for Children," as a memorial of the hero of Khartoum.

AT the recent annual meeting of the Margate Royal Sea-bathing Infirmary for Scrofula, the directors' report stated that the infirmary is approaching its centenary, and they appeal to the public for increased subscriptions in order that the iexpenditure arising from the recent extensions of the building may be met.

SOCIETY FOR THE STUDY AND CURE OF INEBRIETY.—The annual general meeting of the members of this Society was held on the 7th inst., when the president, Dr. Norman Kerr, who occupied the chair, delivered an address, in the course of which he stated that the Association now numbered 279 members. A paper was then read by the secretary, Dr. W. M. Sturrock, contributed by Mr. Crother, of Hertford, Connecticut, honorary secretary of the American Society for the Study and Cure of Inebriety, entitled "The Incipient Stages of Inebriety." A discussion followed, in

the course of which Dr. Farquharson, M.P., pointed out the difficulty of any legislative measures, and also asked for the results of the treatment in the Dalrymple Home for Inebriates. The chairman, in reply, stated that it was difficult to arrive at any satisfactory results from the statistics, as they had only been in existence for about a year; but that of the 49 cases treated in the Home, 50 per cent. of them had remained steadfast and had been restored to their ordinary careers, and 29 per cent. had been greatly benefited. The discussion was continued by Dr. James Stewart, Dr. Morton, and others.

ACTING on the suggestion of a scientific journal in Germany, that neutral tints are beneficial to the eyesight, an enterprising publisher in that country has just issued a book printed in dark-blue ink on pale-green paper.

PRIZE ESSAYS.—The following questions are selected by the Spanish Society of Medical Hydrology as subjects for prize essays, to be sent in by November, 1886:—1. Physical and Clinical Research on the Sulphuretted-Soda Natural Mineral Waters of Spain, and Comparison of Spanish Springs with the principal Foreign Springs. 2. Pathogenic conception of Pellagra, and its Mineral Water Treatment. The prize is £20, and the essays are to be written in Spanish, Portuguese, or French, and are to be signed with a motto only, and accompanied by a sealed envelope bearing the motto outside and the name and address of the author inside. The address of the secretary of the Society is Costanilla de los Angeles 13, Madrid.

MELBOURNE HOSPITAL.—At the annual meeting of the governors of this institution on January 28th, it was stated that the total receipts during 1884 for the purposes of maintenance amounted to £24,302, and the expenditure to £23,277. The number of in-patients admitted was 3334, and of out-patients 13,009. The mortality in the wards was 16·7 per cent., more than one-fourth of the total number of deaths being due to phthisis; and the medical superintendent, in his report, having urged that provision should be made for the treatment of consumptives away from the metropolitan hospital, in the purer air of the country, it was unanimously resolved that steps ought to be taken by the committee of management to carry out the suggestions of the medical superintendent with reference to the removal of phthisical cases, either by establishing a separate institution in the country, or by arrangement with some other institution for their reception.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—At a special supplementary examination, held on Monday, March 16th, and following days, the following gentlemen were successful:—First Professional Examination: T. P. Connolly, C. D. Jones, R. Jones, J. H. Lovely, H. M'Carthy, R. Martin, T. O'Brien, E. O'Neill. Seven were rejected. Second Professional Examination: G. P. Carte, T. G. Goodman, C. M'Donnell, P. J. F. O'Brien, J. C. O'Donnell, J. O'Sullivan, A. V. Shine. Eleven were rejected. Third Professional Examination: W. A. Johnston. At the First Half Examination for the Letters Testimonial of the College, held on March 23rd and following days, the undermentioned gentlemen were successful:—J. A. C. Coen, A. R. T. Craig, I. Duncan, J. D. O'D. Egan, R. Elliott, E. W. Hamilton, J. C. Hines, A. M. Hunt, E. B. Kennedy, A. D. Macleod, A. E. Murphy, V. Nash, H. F. C. Pilcher, J. A. Scully, A. F. Smith, P. Stevenson, W. Stritch, W. Swan, W. E. Waters, J. A. Whitty, T. D. Wylie. Twenty-five were rejected.

Medical Appointments.

Intimations for this column must be sent DIRECT *to the Office of* THE LANCET *before 9 o'clock on Thursday Morning at the latest.*

BARRETT, W. A. H., L.S.A.Lond., has been appointed Assistant House-Surgeon to the Royal Albert Hospital, Devonport.

BOURNS, N. WHITELAW, M.D.Brussels, L.R.C.P.Ed., M.R.C.S., has been appointed Assistant-Surgeon to St. John's Hospital for Skin Diseases, vice Mr. Palmer, resigned.

CAMPBELL, CHARLES M., M.D., C.M., L.R.C.S.Ed., has been appointed Assistant-Physician to St. John's Hospital for Skin Diseases, vice Dr. Boothby Dow, elected a Physician.

DOW, H. BOOTHBY, M.D. St. And., M.R.C.S., has been appointed a Physician to St. John's Hospital for Skin Diseases, vice Dr. Oates, elected a Vice President.

DOWNES, HOWARD, L.R.C.P.Lond., M.R.C.S., has been appointed House-Surgeon to the Victoria Hospital for Children, Chelsea, vice F. H. Hawkins, M.B., C.M., resigned.

DUNCAN, P. T., M.D., B.S.Lond., has been appointed Surgeon to the Croydon General Hospital.

DUNN, HUGH PERCY, F.R.C.S.Eng. (Assistant Ophthalmic Surgeon), has been appointed Pathologist to the West London Hospital.

GLASSINGTON, CHARLES W., M.R.C.S., L.D.S. R.C.S.Ed., has been appointed Lecturer on Dental Materia Medica to the National Dental College, Great Portland-street.

HARRISON, EDWARD, M.A., M.B.Cantab., has been appointed House-Surgeon to the Royal Infirmary, Hull.

JACKSON, HENRY, M.R.C.S., L.S.A.Lond., M.O.H., has been appointed Honorary Surgeon to the North Devon Infirmary, Barnstaple, vice Dr. Ferine, deceased.

LEICESTER, AMBROSE WILLIAM MONTAGUE, M.B., C.M., has been appointed Medical Officer for the Second District of the Eastbourne Union, vice Harold Arthur Tuxford, deceased.

LYNDON, THOMAS, B.Ch.Dub., has been appointed Surgeon to the Wicklow County Infirmary.

MOLYNEUX, HAROLD JOSEPH, L.R.C.P.Ed., M.R.C.S., has been appointed Medical Officer for the Upholland District of the Wigan Union, vice J. L. Molyneux.

MORTIMER, J. D., M.R.C.S., L.S.A.Lond., has been appointed Assistant Medical Officer to the Portsmouth Borough Asylum, vice James Neil, M.D., C.M., resigned.

MURRAY, C. STORMONT, L.R.C.S. &c., has been appointed Administrator of Anæsthetics to the Samaritan Free Hospital.

PRONGER, CHARLES ERNEST, L.R.C.P.Lond., M.R.C.S., has been appointed Honorary Surgeon to the North Devon Infirmary, Barnstaple, vice C. H. Gamble, resigned.

SANCTUARY, THOMAS, M.D., L.R.C.P.Ed., L.R.C.S.Ed., has been appointed Medical Officer to the Workhouse and Fourth District of the Alderbury Union, vice Gowing.

WAINEWRIGHT, BENJAMIN, M.B., C.M.Ed., F.R.C.S.Eng., has been appointed Assistant-Surgeon to the West London Hospital, vice Albert Boyce Barrow, M.B.Lond., F.R.C.S.Eng., resigned.

Births, Marriages, and Deaths.

BIRTHS.

GABBETT.—On the 26th ult., at Gibraltar, the wife of Surgeon-Major Poole R. D. Gabbett, Medical Staff, of a daughter.

HICKEY.—On the 5th ult., at the Royal Naval Hospital, Esquimalt, British Columbia, the wife of Staff-Surgeon L. Canning Hickey, M.B., of a daughter.

HUNT.—On the 3rd inst., at Queen's-road, Dalston, the wife of Joseph W. Hunt, M.D.Lond., of a son.

ILLINGWORTH.—On the 31st ult., at 1, Crowther-terrace, Clayton-le-Moors, the wife of C. R. Illingworth, M.D., of a daughter.

PARAMORE.—On the 1st inst., at Hunter-street, Brunswick-square, W.C., the wife of Richard Paramore, M.D., of a son.

RICHARDS.—On the 1st inst., at 38, Arundel-square, Barnsbury, N., the wife of C. C. Richards, M.D., of a son.

MARRIAGES.

CHAMP—SCHAEFFER.—On the 4th inst., at Holloway Chapel, London, John Howard Champ, M.D.Lond., son of J. Champ, Esq., of Chelmsford, to Josephine, eldest daughter of the late Joseph Schaeffer, of Heidelberg.

DUNLOP—GALT.—On the 8th inst., at the Alexandria Hotel, Bath-street, Glasgow, by the Rev. Fergus Ferguson, M.A., of Queen's-park U. P. Church, and the Rev. D. W. Forrest, M.A., of Hamilton, Thomas C. Cameron Dunlop, M.B., C.M., of Newmilns, Ayrshire, to Amy, second daughter of W. M. Galt, Esq., of The Brook, Enniskillen, Ireland.

YEATMAN—BROWNE.—On the 12th Feb., at St. Luke's Church, South Melbourne, by the Rev. R. B. Dickinson, John W. Yeatman, M.R.C.S.Eng., son of the Rev. E. K. Yeatman, M.A.Oxon., of Auburn, South Australia, to Katherine Maude, fourth daughter of the late John E. Browne, of Northcote, Melbourne.

DEATHS.

BOND.—On the 2nd inst., at Mentone, France, George Weddall Bond, M.R.C.S., third son of the late Rev. R. Bond, Rector of Pulham St. Mary the Virgin, Norfolk.

HOWKINS.—On the 20th ult., at Torquay, Thomas Howkins, M.R.C.S., late of Bennett's-hill, Birmingham.

POPE.—At South-crescent, Bedford-square, Joseph John Pope, M.R.C.S.

SANKEY.—On the 27th Jan., on board the *Chimborazo*, in the Red Sea, from inflammation of the lungs, George Sankey, M.R.C.S. & L.S.A.Lond., of Maidstone, aged 54.

STURGE.—On the 2nd inst., at Rue Longchamp, Nice, Emily Bovell Sturge, M.D. Paris, Officier d'Académie, daughter of the late John Roache Bovell of Demerara, and wife of William Allen Sturge, M.D.

WHITEHEAD.—On Good Friday, the 3rd inst., at his residence, Fairlands, Sutton, Surrey, James Whitehead, M.D., late of Mosley-street, Manchester, in his 74th year.

WILKIE.—On the 3rd inst., at Paris, David Elliot Wilkie, M.D., of Rathobyres, third son of the late Rev. Daniel Wilkie of Rathobyres, Minister of New Grey Friars, Edinburgh.

N.B.—*A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.*

Medical Diary for the ensuing Week.

Monday, April 13.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10.30 A.M., and each day at the same hour.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1.30 P.M., and each day at the same hour.

ST. MARK'S HOSPITAL.—Operations, 2 P.M., and on Tuesdays at the same hour.

HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M., and on Thursday at the same hour.

METROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.

ROYAL ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN.—8 P.M. Mr. J. Bland Sutton: Injuries and Diseases of the Jaws in Wild Animals.—Casual communications by Messrs. W. A. Hunt, Wenland Pedley, A. S. Underwood, and F. H. Weiss.

MEDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Whipham: A case of Myxœdema with the Microscopical Appearances of some of the Organs.—Dr. Hughes Bennett: A case of Brachial Monoplegia due to a Lesion of the Internal Capsule.

Tuesday, April 14.

GUY'S HOSPITAL.—Operations, 1.30 P.M., and on Friday at the same hour. Ophthalmic Operations on Mondays at 1.30 and Thursdays at 2 P.M.

ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 4 P.M.; Friday, 2 P.M.

CANCER HOSPITAL, BROMPTON.—Operations, 2.30 P.M.; Saturday, 2.30 P.M.

WESTMINSTER HOSPITAL.—Operations, 2 P.M.

WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.

ROYAL INSTITUTION.—3 P.M. Prof. Gamgee: Digestion and Nutrition.

ANTHROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND.—8 P.M. Dr. J. G. Garson: On the Inhabitants of Tierra del Fuego.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—8.30 P.M. Mr. Lunn and Dr. Benham: Case of Aneurysm of Abdominal Aorta, distal compression for four hours and three-quarters under chloroform, cure of aneurysm, death from gangrene of jejunum on the eleventh day.—Mr. Henry Morris: A case of Aneurysm of the Abdominal Aorta leading to Gangrene of the Lower Extremity.—Dr. Beevor: Two cases (Progressive Muscular Atrophy and Infantile Paralysis) illustrating the Localisation of Motor Centres in the Brachial Enlargement of the Spinal Cord.

Wednesday, April 15.

NATIONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.

MIDDLESEX HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.—Ophthalmic Operations on Tuesdays and Thursdays at 1.30 P.M.

ST. MARY'S HOSPITAL.—Operations, 1.30 P.M. Skin Department: 9.30 A.M., on Tuesdays and Fridays.

ST. THOMAS'S HOSPITAL.—Operations, 1.30 P.M., and on Saturday at the same hour.

LONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.

GREAT NORTHERN CENTRAL HOSPITAL.—Operations, 2 P.M.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2.30 P.M.

UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M.; Saturday, 2 P.M. Skin Department: 1.45 P.M.; Saturday, 9.15 A.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 3 to 4 P.M.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—3 P.M. Mr. R. Brudenell Carter: Eyesight in Schools.

Thursday, April 16.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M.

ST. BARTHOLOMEW'S HOSPITAL.—Surgical Consultations, 1.30 P.M.

CHARING-CROSS HOSPITAL.—Operations, 2 P.M.

NORTH-WEST LONDON HOSPITAL.—Operations, 2.30 P.M.

ROYAL INSTITUTION.—3 P.M. Prof. Tyndall: Natural Forces and Energies.

HARVEIAN SOCIETY OF LONDON.—8.30 P.M. Dr. R. W. Burnet: Cases of Ulcerative Endocarditis, with remarks.—Mr. J. Ernest Lane: Hæmophilia.

Friday, April 17.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1.30 P.M.

ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.

KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—7.30 P.M. The Council will present a report on the Rivers Pollution Bill and the Water Companies Regulation of Powers Bill.—Dr. Thomas Stevenson: Sewage Disposal.

ROYAL INSTITUTION.—9 P.M. Prof. S. P. Langley: Sunlight and the Earth's Atmosphere.

Saturday, April 18.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.

ROYAL FREE HOSPITAL.—Operations, 2 P.M.

ROYAL INSTITUTION.—3 P.M. Mr. W. Carruthers: Fir-trees and their Allies.

Notes, Short Comments, & Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editor."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe, or recommend practitioners.

Local papers containing reports or news-paragraphs should be marked.

Letters relating to the publication, sale, and advertising departments of THE LANCET *to be addressed "To the Publisher."*

NEW FARINACEOUS SEED.

A LETTER from M. Sacc of Cochabamba to the Paris Academy of Sciences reports upon a new alimentary substance the composition of which is remarkable. The seed which is richest in nitrogenised substances is that of the Bolivian cotton tree. Its analysis shows 23·70 per cent. of fibrine and 6 per cent. of caseine. When ground, there is only 3 per cent. of loss, a yellow flour being 56½ per cent., and a black bran 40½ per cent. M. Sacc remarks that this flour ought to be particularly suitable for pastry, as it would to some extent replace milk. It is also of service in sugar manufacture, as a substitute for carbonic acid. It is likewise good for sweets, &c. As the production of cotton seed is very large, its utilisation would be of great alimentary importance.

Dr. C. Morfit.—We will try to find a place for the article in an early number.

"EFFECTS OF HANDLING DYNAMITE."

To the Editor of THE LANCET.

SIR,—Surgeon-Major Colson's letter on this subject reminded me of having read of the same thing before; and on referring to my notes I find that Dr. Colquhoun (*Australian Medical Journal*, June, 1881) found symptoms of this kind result, as he believed, from the vapour of imperfectly consumed nitro-glycerine in the air of mines where dynamite was used, and that Dr. R. B. Nevitt (*Canadian Journal of Medical Science*, February, 1882) reported the case of a man aged forty, a contractor, in the habit of using dynamite cartridges, who suffered from headache, tinnitus, and palpitation, which symptoms disappeared when he took the precaution to wear gloves and avoided a previous trick of tasting his fingers with his tongue to see if all the dynamite was washed off. I think it is very doubtful if nitro-glycerine acts through the skin or the atmosphere; and I would suggest that the utmost caution should be used to prevent actual contact of the dynamite with the eyes or mouth, which may easily occur if the user is not forewarned of the danger.

I am, Sir, yours obediently,

Birmingham, April 4th, 1885. ROBERT SAUNDBY, M.D.

To the Editor of THE LANCET.

SIR,—In reply to Surgeon-Major Colson's note, "dynamite headache," as it is called, is very similar to that produced by amylic nitrate, and, so far as I know, is inseparable from the use of the explosive, until immunity is produced either by prolonged use or idiosyncrasy; but no permanent injury results. With regard to the cure, there is none, except cessation from working with it; but brandy-and-water will mitigate it, and sleep generally remove it. Some physiological notes were published in THE LANCET some time ago.

I am, Sir, yours faithfully,

WALTER WICKHAM,

Surgeon to Nobel's Explosives Co., West Quarter Factory.

Polmont Station, N.B., April 6th, 1885.

THE INDEX MEDICUS.

As announced in a recent issue, the publication of the Index Medicus will be continued by Mr. G. S. Davis of Detroit. On account of the delay required to perfect the new arrangement, the first number of the journal for the current year will comprise the literature of January, February, and March, after which it will appear monthly as usual. At the end of the year, in addition to the usual annual index of names, subscribers will be furnished with an index of subjects to the volume.

A Constant Reader.—A patient suffering from a *small* irreducible strangulated femoral hernia is better without a truss, as the pressure tends to cause inflammatory adhesion and constriction of the bowel, and so increases the danger of internal strangulation. The case as described by our correspondent reads more like one of incarcerated (obstructed irreducible) than strangulated hernia. That being so, enemata (not purges), spare liquid diet, local application of ice, and complete rest constitute the appropriate treatment. In most cases of strangulated hernia, unless gangrene of the bowel is feared, it is customary to attempt reduction under an anæsthetic before resorting to the more severe operative procedure; and this rule applies with greater force to obstructed hernia. At the same time, each case must be judged on its merits.

A. B. C.—Wooton's Guide to the Medical Profession (U. Gill, Strand, London) would assist our correspondent.

Beta.—Yes, in an early number.

"APPLICATION OF MIDWIFERY FORCEPS."

To the Editor of THE LANCET.

SIR,—I should be the last in the world to despise the aid given by forceps in cases where they are really necessary, but I think there is a growing tendency among general practitioners to shorten labour by means of the forceps, especially if they be adepts in the use of the instruments. How many women there are who have to thank their impatient medical attendant, in, say, a first confinement, for a perineum ruptured into the anus—a life-long discomfort! The doctor is rarely blamed; as a rule, a woman is only too glad to get over her troubles at any price, and the medical attendant is lauded "to the skies" for his cleverness in bringing matters so quickly to an apparently successful issue. Further, I would ask those who make the diseases of women a specialty, how many of the various flexions of the uterus are due to the application of the forceps? and, again, how much their use conduces to malposition of the organ? I cannot but think that many of these troubles are due to the meddlesome, nay wicked, interference with what nature would successfully accomplish, and very much better than the doctor. In this opinion I am supported by the fact that uterine troubles in the rural districts are very rare in comparison with those existing in town practice, nature, not the doctor, doing the work.

It is argued by many that deformities in women are more common than they were formerly. I, for one, consider that Englishwomen of the present day are as well developed and as capable of going through maternity naturally as their grandmothers were. It is an easy matter, however, to point out errors, but to apply the remedy is more difficult. But here the remedy lies in ourselves, our own judgment, and the recollection of what is due to those who place themselves with such trust and confidence in our hands.—Yours faithfully,

W. AYLMER LEWIS, F.R.C.S.

Willow-street, Oswestry, April 7th, 1885.

To the Editor of THE LANCET.

SIR,—With reference to the above subject, permit me to describe a method of applying the forceps which I have adopted and practised for many years. I apply the lower blade first. The patient's right knee is then drawn up, and the left leg extended and drawn outwards. The upper blade is then introduced, using the left hand, the forefinger of the right hand being in the vagina to direct the blade over the head and gently press the convex edge of the blade. In this way it easily goes into its proper position and locks with the other. Extraction is then made in the ordinary manner.—Your obedient servant,

Kingussie, March, 1885. J. C. ORCHARD, L.R.C.S. Edin.

B. will see that the subject to which he has been so good as to direct our attention has not escaped our notice.

T.—Bath or Buxton.

AN OLD MEDAL.

To the Editor of THE LANCET.

SIR,—I should feel much obliged to any of your correspondents who would give me information as to a medal in my possession, of which the following is a description: Diameter 1⅛ in. Obverse—A pot of flowers in high relief, standing on a label, on which is the date, also in relief, 1684, and engraved on the label, evidently prepared for that purpose, the inscription, "MR. JOANNES. DE. WALL." In the exergue are the words, 'HORTUS MEDICUS." Reverse—A skeleton with scythe and hour-glass, standing in a flowery mead. The botanic gardens in Chelsea (commonly called the "Physic Garden") were not enclosed till 1680, so that a ticket of admission, which this medal evidently is, would have no *raison d'être* in 1684. Yet, I feel no doubt that its design and execution are English.

I am, Sir, yours obediently,

April 6th, 1885. M. U.

THE RUPTURE OF BLOODVESSELS.

MM. GRÉHANT and QUINQUAUD have reported to the Paris Academy of Sciences their experiments proving that the pressure necessary to cause the rupture of arteries is much greater than that to which they are normally subjected. The carotid artery of a dog required from thirty-five to fifty-five times the normal pressure of the blood, and the jugular vein from thirty-two to forty-five times the usual force.

Practitioner should remonstrate with the chemist, and, failing to get satisfaction, should complain of his conduct to the President of the Council, who is at present trying to regulate the sale of poisons by legislation.

"VEGETABLE FOOD FOR CHILDREN."

To the Editor of THE LANCET.

SIR,—Perhaps you will allow me to make a remark or two upon your notice under the above heading of the dinner given by Mr. S. Morley, M.P., under the auspices of the National Food Reform Society. The dinner mentioned was given with a view of showing the people of Leigh that a good dinner could be provided at small cost and yet be pleasing, wholesome, and sufficient. The menu was "Scotch broth," "lentil sandwiches," "lentil fritters," with cauliflower, potatoes, and "brown sauce," "Albert pudding," with white sauce. Whole wheat-meal bread was also given. The entire cost of dinner (for food) was under fourpence halfpenny per head. Mr. Morley and all to whom I have spoken have pronounced the dinner as having been first-class in every particular, and a good lesson in practical thrift.

In regard to non-flesh eaters being non-drinkers, I may mention that previously to my giving up "meat" I was fond of "a glass," but in three months I lost all desire or taste for strong drink. I could say much on the head of experience, as I have now been an abstainer from "meat" for upwards of seven years, and I have lost many of my former complaints. I may say that I am quite willing to place myself in the hands of any medical gentleman for the purpose of experiments in dietetics, and that without any compensation whatever. In conclusion, allow me to state that the National Food Reform Society will give its thrifty dinners when asked so to do, provided a hall, &c., is furnished free of cost. I am, Sir, yours faithfully,

F. P. DOREMUS,

Hon. Secretary, National Food Reform Society.

Finsbury-square Buildings, E.C., April 4th, 1885.

*** While we cannot agree that vegetarianism is a sound enough principle in dietetics to be generally adopted, we freely admit that an occasional change of fare of this kind is both wholesome and agreeable. Some persons also, even adults, thrive better, as a rule, on vegetable than on animal diet; or, at all events, on a diet in which vegetables markedly predominate. Such are those of gouty constitution. With regard to the effect of food on the liking of alcohol, no conclusion, we think, can yet be arrived at. Possibly the flavour of fruit may satisfy some as a substitute for its more potent derivative.—ED. L.

NURSING STATISTICS.

M.D. asks: "Will any of your readers oblige by referring me to a source of information regarding the cost of nursing (apart from other sources of maintenance) in the large general hospitals of the metropolis and the provinces."

E. De Manin.—There is no particular objection to gas-stoves, so long as proper provision is made for carrying off the products of combustion.

RECREATION FOR THE SOLDIERS IN THE SOUDAN.

To the Editor of THE LANCET.

SIR,—You were good enough to put a paragraph in THE LANCET of March 21st, saying that I would be glad to receive contributions of suitable literature for the soldiers in the Soudan. I now desire to thank the public, amongst whom are a few medical men, for the parcels they have sent; and as they have a right to know what I have done, I may say that since March 21st I have sent 5 cwt. of books, dominoes, draughts, and a few pipes to Suakim, about 4 cwt. to Dongola, and about 4 cwt. to Wady Halfa, and I think I shall be able to forward about 4 cwt. next week. I know from experience how a newspaper, six weeks old even, is valued in such a place as the Soudan, and consequently have some feeling for our brave soldiers who are now fighting our battles and suffering all manner of privations. Those who have kindly sent parcels please accept my thanks. I am, Sir, yours truly,

258, St. Philip's-road, Sheffield, April 4th, 1885. JOSIAH WILLIAMS.

THE DEBATE ON CHOLERA.

Mr. J. B. Scriven writes that the report of his remarks on cholera in our last issue, page 616, is incorrect. His argument as to the cause of the viscidity of the blood may be stated thus: The almost unlimited power of absorbing fluid which the blood possesses during health has not been proved to continue in full force during an attack of cholera; so that in that disease much of the water discharged in the stools may possibly not be replaced in the blood.

Calyx.—1. No; choice should be made beforehand.—2. In London, two or three days before the examinations begin.—3. We are not aware of their having been published.

ILLEGIBLE PRESCRIPTIONS.

A CORRESPONDENT from West Australia has forwarded us a prescription which, written by a brother practitioner, was handed in to his dispenser to be made up. The writing is so bad, and the figures denoting the quantity of each drug to be used so blotted and confused, that the medicine could only be made up by the knowledge of doses possessed by the dispenser. This fault of writing, through haste or carelessness, illegible prescriptions is one shared by many medical men; but it is nevertheless a grave one, and one that has frequently ere now led to serious consequences.

J. J. J.—A burn which destroys the skin, superficial fascia, and muscles must necessarily be followed by profuse suppuration and cicatricial contraction. The one described could not by any possibility have healed in a month. Where home comforts and careful nursing can be obtained, we consider the patient best treated out of hospital.

E. H. should consult his medical attendant.

Iron.—We do not give advice.

MEASLES IN GUERNSEY.

To the Editor of THE LANCET.

SIR,—I hope I am not in error in accepting your note under the above heading in your last issue as an invitation to make a personal explanation.

At the end of the Table of Contents in each issue of the *Glasgow Medical Journal* the following notice appears:—"Authors of original articles may, by applying to the printer, obtain twenty-five reprints of their articles gratis, and additional copies at a small cost." I obtained the twenty-five copies, and detail for your information the distribution which took place in Guernsey. Drs. Corbin, Crewe, Constantine, Conclean, Glasse, Thornhill, three personal friends (none of whom can be referred to by your correspondent) who furnished me with statistics concerning the number of cases in the schools, and the following officials: the Lieut.-Governor of Guernsey, the Bailiff of Guernsey, the Chief Constable of Guernsey, and Dr. Le Page, each received a copy of the *Journal*. I defy your correspondent to supplement this list. The copies sent to the Lieut.-Governor, the Bailiff, and the Chief Constable were sent officially, and were marked, as the enclosed copy is, on pages 2 and 3, directing their attention to the comments there on the sanitary condition of the place, a subject which has occupied them much during the past winter, and on which medical opinion was invited. The Lieut.-Governor and the Chief Constable are not patients of mine, and they received their copies addressed to them as officials at their offices.

The allegation that the recent epidemic of measles differed from the description given of it in my paper will not be much credited in Guernsey. Only those who failed to observe, or were blinded by prejudice, could make a contrary statement.

I am afraid that your notice will render it difficult for me to keep my comments on the sanitary condition of the town within the official limits which I had intended even until my reply reaches your columns. The statements made in my paper are well known to be correct, and could only have done public good while their distribution was limited to those concerned in the local sanitary administration.

I am, Sir, your obedient servant,

Guernsey, April 4th, 1885. J. AIKMAN.

To the Editor of THE LANCET.

SIR,—My attention has been drawn to an extract from THE LANCET of the 4th inst., in which exception is taken to Dr. Aikman's action in sending copies of his paper in the *Glasgow Medical Journal* on the Epidemic of Measles in Guernsey to the patients of another medical man. As I received a copy of his paper from Dr. Aikman, and may be one of the recipients alluded to, I ask your permission to state that I, as Lieut.-Governor of Guernsey, have publicly interested myself in the sanitary state of the island, and have no idea that the paper was sent to me except in my official capacity.

I have the honour to be, Sir, your obedient servant,

H. A. SAREL, Major-General.

Bournemouth, April 7th, 1885. Lieutenant-Governor of Guernsey.

To the Editor of THE LANCET.

SIR,—At Dr. Aikman's request, I hereby beg to state that I received a copy of the reprint of his notes on a recent epidemic of measles in Guernsey, addressed to me at the Constable's Office in my official capacity; also that the copy was marked at the passages referring to the sanitation of the town.—Pours faithfully,

Guernsey, April 4th, 1885. JULIUS A. CAREY, Chief Constable.

*** We think Dr. Aikman's letter satisfactory. Moreover, we have read the paper on Measles, and cannot see anything in it to justify the complaints made. The epidemic had been very extensive and rather severe, and was the more noticeable as being rare in the island.—ED. L.

PREVENTION OF CARBUNCLE IN CATTLE BY VACCINATION.

To the Editor of THE LANCET.

SIR,—I should be much obliged if any of your readers could tell me where I can get lymph for "vaccinating" cattle as a preventive against carbuncle. I believe Pasteur is the discoverer of the method and preparation.

I am, Sir, your obedient servant,

April 7th, 1885. F. G. V.

WHOOPING-COUGH.

Mr. C. Clark Burman, L.R.C.P. & S. Ed. (Belford, Northumberland), solicits replies to the following questions:—(1) Are the paroxysms of whooping-cough more frequent always at night, whether the patient sleeps or not? (2) At what hours of the night are they most apt to occur? (3) What relation do they bear to the sleep of the child—i.e., during profound sleep or otherwise? (4) What circumstances appear to induce them?

Mr. W. Holderness.—1. Berkeley Hill's work on Bandaging and Minor Surgery.—2. Lewis S. Pilcher's Treatment of Wounds. The latter, an American work, is one of the best on the subject with which we are acquainted. It is published by Messrs. William Wood and Co., 56, and 58, Lafayette-place, New York.

THE BIRMINGHAM MEDICAL INSTITUTE.

To the Editor of THE LANCET.

SIR,—The interesting account, given in to-day's issue of THE LANCET, of the Birmingham Medical Institute, ought to make one glow with pride at having the privilege of living even within two or three miles of such a noble and generous Society. But, Sir, there is another side to the picture, and this, I am sure, out of regard for your time-honoured maxim, *Audi alteram partem*, you will allow me to present with the pen of a truthful but not unfriendly critic.

Rather more than a year ago a "registered practitioner" applied to the sub-librarian of the above-named Society for information as to the steps to be taken to enable him to avail himself of the library. He was told by that official that the payment of a guinea was the chief thing required, although there was another ceremony to be observed, which, however, was a "mere form." The ceremony thus described as a "mere form" was the signing by six members of the institute of a paper left in the reading room for that purpose. The "registered practitioner" paid the fee, and in due course two signatures were affixed to the paper. Then in a short time the document disappeared altogether, leaving the "registered practitioner" to believe that the "mere form" had been duly complied with. His surprise, however, was great when, three months afterwards, on applying for a book, he was told that he was not a member. On further inquiry he learned that the signatures referred to had been withdrawn at the dictation of a "distinguished hospital surgeon," who had forbidden his name to be divulged. I regret to say that the "registered practitioner" lost his temper on this occasion, though I do not much wonder that he yielded to this infirmity. To have been blackballed by a ballot would have been intelligible, and timely notice would have been given of the result; but the above-described method of procedure seems both ill-natured and illiberal. The "registered practitioner" has no complaint to make against the officials of the Society, either honorary or paid, but he would like to see the "distinguished hospital surgeon" emerge from his Olympian cloud and give some explanation of his conduct.—Yours obediently,

Birmingham, April 4th, 1885. WILLIAM J. NOTLEY, M.D.

F.R.C.S.—Reports from Her Majesty's Representatives at European Courts and in the United States on the Working of the Lunacy Laws in the Countries in which they reside. Miscellaneous, No. 1 (1885). Messrs. Hansard, 13, Great Queen-street, W.C.

Mr. E. Playter.—We do not think it would serve any good purpose to open the discussion our correspondent suggests. There can be no doubt of "the present usefulness of the practice."

"A HALFPENNY A WEEK."

To the Editor of THE LANCET.

SIR,—In answer to an annotation under the above heading, which appeared in your issue of March 21st, the Committee of the Working Men's Medical Society at Sheerness would like to correct the serious errors made in that statement. As to there being some sixty applicants who applied for the position as advertised in THE LANCET of March 7th, it is due to them and others to know that the working men of Sheerness did not expect a medical gentleman to work on such unremunerative terms as appeared in the paragraph alluded to. A similar Society to ours has been in existence this past forty years; it is true our contribution is only one halfpenny per week, but it is for each individual entered, which on a little consideration will show that the scheme is very feasible. Let us give a short digest of how our Society now stands, and we think it will conclusively show the different gentlemen who applied that what we stated in our advertisement was more than correct.

The Society was inaugurated on March 1st, 1885; our present number of members (March 29th) is about 3800, which gives £111 per annum, the accouchement fee for members' wives are paid in addition to these contributions, which would equal another £150, making a total of about £560 per annum; private practice is also allowed. None of the above amounts are deducted for working expenses.

In reference to the paragraph alluding to the Portsmouth Association, it was stated at the meeting that they paid their doctors about £300 and £400 per annum each, and not, as represented, that amount divided between them. We hope this statement will satisfy those gentlemen who have written to us on this subject since the erroneous insertion of March 21st. I am, Sir, yours respectfully,

THOS. LOVATT, Secretary.

For the Committee of the Working Men's Medical Society.

Marine Town, Sheerness, April 6th, 1885.

A CAUTION.

Mr. Roche Lynch, of Boyle-terrace, Holland-park, would caution his professional brethren against a "broad-shouldered man, forty or fifty years of age, with sandy whiskers," who, representing himself as an agent of a certain firm, called at his house under pretence of seeking information about some person, and who, being shown into Mr. Lynch's consulting-room, made off with a surgical instrument which happened to be lying on the table.

A Subscriber will find a whole series of the measurements of which he is in quest on pp. 655–657 of Woodman and Tidy's Handbook of Forensic Medicine and Toxicology. Churchill, 1877.

M.B.—Jevons' Logic, Ribot's Psychology, Killick's Abstract of Mill.

MEDICAL PRACTICE IN THE UNITED STATES.

To the Editor of THE LANCET.

SIR,—If any of your readers have had experience of medical practice in the Southern States of N. America, perhaps they will kindly inform me through your columns what prospects there are in any of the large cities for a London physician, and what qualifications he must obtain in the United States to permit of his practising there, provided he is a L.R.C.P. and M.R.C.S.L. I am aware that in Canada an English medical man must take out a licence to practise before he can put up his "shingle" in the colony. Relying upon your usual courtesy to insert this letter, I remain, Sir, yours obediently,

April 7th, 1885. MEDICUS.

A CORRECTION.

To the Editor of THE LANCET.

SIR,—Most misprints may be passed over as unimportant. But in the abstract of my paper read at the Medical Officers of Health Society, page 622, third line from top, "the element of *lime*" should be "the element of *time*," and I fear, unless corrected, it will give the impression that I think highly of lime as a disinfectant.—Yours truly,

Wellington-road, N.W., April 5th, 1885. A. WYNTER BLYTH.

"HYDROCHLORATE OF COCAINE."

To the Editor of THE LANCET.

SIR,—In reply to Mr. Symes's letter, which appeared in your last issue, I beg to state that the filtered cocaine solution which I mentioned in my first communication to THE LANCET has been used at this hospital with the most satisfactory results.—Yours faithfully,

Sussex Eye Hospital, April 8th, 1885. J. CHURCHYARD.

ERRATUM.—In Mr. B. Roth's remarks, page 619 of our last issue, for "Fletcher's bags" read "*Fleming's* bags."

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Dr. Wilks, London; Dr. W. Squire, London; Dr. Saundby, Birmingham; Dr. M. Oxley, Liverpool; Mr. T. Holmes, London; Mr. Rushton Parker, Liverpool; Professor De Chaumont, Netley; Mr. Husband, Leeds; Dr. Goodhart, London; Prof. Wharton Jones, Ventnor; Dr. Eben. Watson, Glasgow; Mr. J. The Publisher cannot hold himself responsible for the return of testimonials, &c., sent to the office in reply to advertisements; copies only should be forwarded.

NOTICE.—Advertisers are requested to observe that it is contrary to the Postal Regulations to receive at Post-offices letters addressed to initials only.

An original and novel feature of "THE LANCET General Advertiser" is a special Index to Advertisements on page 2, which not only affords a ready means of finding any notice, but is in itself an *additional* advertisement.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Answers are now received at this Office, by special arrangement, to Advertisements appearing in THE LANCET.

Terms for Serial Insertions may be obtained of the Publisher, to whom all letters relating to Advertisements or Subscriptions should be addressed.

Advertisements are now received at all Messrs. W. H. Smith and Son's Railway Bookstalls throughout the United Kingdom, and all other Advertising Agents.

Tables of Contents, with the Index of Advertisements, for each Number can be had on application to the Publisher.

Agent for the Advertising Department in France—J. ASTIER, 66, Rue Caumartin, Paris.

Croonian Lectures

ON THE

HYGIENIC AND CLIMATIC TREATMENT OF CHRONIC PULMONARY PHTHISIS.

Delivered at the Royal College of Physicians,

BY HERMANN WEBER, M.D.,

PHYSICIAN TO THE GERMAN HOSPITAL.

LECTURE III.

5. Climates. — Purity of Air the most important element. — Floating Matters. — Climates of Elevated Regions. — Objections met. — General Characters. — Physiological and Therapeutical Actions. — Swiss Alps. — Peruvian Andes. — Rocky Mountains. — South African Highlands. — Home Climates.

MR. PRESIDENT AND GENTLEMEN,—It is difficult to say anything new on the treatment of phthisis by *climate*, as the literature on the subject is rich in good articles. I need only mention the names of Sir James Clark, Walsh, J. E. Pollock, King Chambers, J. H. Bennet, C. J. B. Williams and C. Theodore Williams, Thorowgood, F. and P. Niemeyer, Rohden, Jaccoud, Biermann, Thilenius, H. Hassall, Sée, Symes Thompson, Marcet, Clifford Allbutt, Burney Yeo, Sparks, Denison, Solly, and Tyndale. The remarks which I am going to make can only be very fragmentary.

The difference between different cases of phthisis is so great that it is impossible to lay down fixed rules for climatic treatment. In deciding between different climates and localities, the circumstances connected with the etiology, the stage of the disease, the amount of destruction, and the complications with diseases of other organs are very important; but still more so the distinction between a weak and a strong constitution, an excitable or a torpid nature—between progressive and retrogressive, active or stationary, cases. Mental peculiarities, too, ought not to be overlooked; nor the habits of the invalid and the circumstances in which he has lived. Unlike, however, as different invalids are in these and other points, in all of them we must bear in mind that we have to deal with raw and ulcerated surfaces in the respiratory passages; surfaces which in most cases, at all events, are infected by a specific microbe, and are very susceptible to all impurities of the atmosphere, and especially to the microbe element, which abounds wherever organic decomposition, and particularly putrefaction, takes place, and wherever there are congregations of human beings and animals in shut-up localities. Hence it is clear that *purity* or an *aseptic state* of the air is the first demand which we ought to make on the climates to which we send persons affected with phthisis. Temperature, the degree of moisture, atmospheric pressure, light and sunshine, electricity, wind, frequency or absence of rain and snow, nature of soil, elevation above the plain or the sea, which in their varying combinations form the different climates, are each and all-important agents in the climatic treatment, as I have endeavoured to show elsewhere; but none is so essential to the consumptive patient as the purity of the atmosphere. After what I have said before on the necessity of pure air and its renewal in rooms, it is scarcely necessary to add here that in every climate the position and the internal arrangements of the house, and particularly of the rooms in which the invalid is to live, are as important as the character of the climate of the place. In former years the composition of the air in its influence on health was judged principally by the amount of oxygen, nitrogen, carbonic acid, ammonia, and water, but of late attention has been forcibly directed to the amount of *floating matter* in the air by Ehrenberg, Pasteur, Tyndall, Maddox, and others; and a great accession to our knowledge and a fuller appreciation of the influence of the atmosphere has been obtained by the interesting labours of Miguel at the Observatoire de Montsouris, near Paris, to which Professor Sée has directed my attention, and the result of which has been mentioned by Dr. Poore in his Cantor lectures, already alluded to. Miguel gives us the following interesting table of the number of bacteria found in ten cubic metres of air taken as nearly as possible at the same time in July, 1883:—

1.	At an elevation of from 2000 to 4000 metres	None
2.	On the lake of Thun (560 metres)	8·0
3.	Near the Hôtel Bellevue, Thun (560 metres)	25·0
4.	In a room of the Hôtel Bellevue	600·0
5.	In the Park of Montsouris, near Paris ...	7600·0
6.	In Paris itself (Rue de Rivoli)	55,000·0

This table shows clearly, as I have already pointed out, the difference not only between a high and low elevation and between town and suburb, but also between in-door and out-door air; the air in a room of the Hôtel Bellevue containing twenty-four times as many microbes as the air in the grounds outside. The difference between the air on the lake of Thun (8·0) and on the shore—i.e., the grounds of the Hôtel Bellevue (25·0)—is likewise significant; and the low rate on the former may be ascribed to the distance from the sources of organic decomposition. We may reasonably infer that a still greater rarity of microbes will be found in the air on high sea. Similar researches into the purity of the air are being energetically pursued at Berlin, but I am not yet acquainted with the result.

Another point of consideration is, How far do climates and health resorts assist the invalid in improving the general nutrition and power of resistance? This depends to a great degree on their enabling the invalid to be much in the open air and take active exercise without risk of chills and consequent complications. Not all the climates, however, which allow the invalid to be much in the open air are at the same time conducive to active exercise. Some are apt to produce a feeling of languor and diminished inclination for food, while others raise the nervous system, improve the appetite, digestion, sanguinification and muscular energy, and facilitate the elimination of used-up matter. We may, in some points, compare climates with medicines. There are such medicines, as morphia, which soothe the cough and procure sleept, but check the appetite and nutrition in many people. Antipyrin has a wonderful power in subduing pyrexia, but in almost all my trials of its effect on the pyrexia of consumptive patients it has entirely suppressed the appetite. Such medicines ought, therefore, to be avoided in the majority of hopeful cases of phthisis, because the improvement of the nutrition is the first demand. So there are agreeable climates which soothe the cough, but diminish the appetite and the inclination to take exercise, and can, therefore, be recommended only in exceptional cases. On the other hand, bitter remedies and tonics do not soothe the cough; but if they improve the appetite they often exercise a beneficial influence on the course of phthisis. In the same way cold does not soothe cough, but, on the contrary, sometimes produces it at first; but if it improves the appetite of the consumptive person, and enables him to take more exercise, it improves the nutrition, and thus exercises a beneficial influence on the course of phthisis. The consideration of such qualities of climate is all-important in the treatment of phthisis, though these characters are not shown by meteorological tables, however carefully prepared; they must be learned from personal observation and from carefully watching invalids and their healthy companions. In these points lies the difference between what are popularly called relaxing and bracing climates. We will not, however, disregard meteorological tables and descriptions, for from these we often learn important facts about the nature and strength of wind, the frequency of mist and rain, the conditions of temperature, the degree of humidity, the amount of sunshine, so that we can avoid sunless and depressing climates, with frequent cold wind, mist, rain, and drizzle, which prevent the invalids from taking a sufficiency of out-door exercise. Unsatisfactory, however, as these influences are there are others to be much more dreaded, as crowding together of many human beings, stagnation of air, presence of decaying substances, organic dust, lowness of situation, and dampness of soil (Bowditch and Buchanan).

Many people still cling to the idea that cold is injurious and warmth curative in phthisis, but this idea is quite incorrect. Another idea that equable climates are the best in the treatment of phthisis should likewise be much restricted. The most important point of all good climates in phthisis, as I have said before, is purity of air. This is to be found, first, on elevated regions; second, in the desert; third, on the sea. The first two are usually considered

under the great division of inland climates, the third under marine climates. In rapidly glancing over these divisions, I shall have the opportunity of mentioning some other localities which are used as health resorts in phthisis, although they could not claim pure air, or air of an aseptic character, as one of their prominent features.

Allow me, gentlemen, to begin with the climates of elevated regions (altitude or mountain climates), which only in comparatively recent times have come into favour in Europe; although they were used in Peru at an earlier period (Archibald Smith). They were somewhat roughly treated in the beginning. A justly esteemed author on diseases of the lungs, for instance, in 1871 calls the plan of treating consumptive patients by long residence in the Alps "a startling quasi-sensational novelty in climatic therapeutics" in reference to a paper of mine "On the Treatment of Phthisis by Prolonged Residence in Elevated Regions" in the Medical and Chirurgical Transactions of 1869. In further discussing this plan the same author speaks of the winter in an "elevated site in Switzerland" as a sojourn "amid mist, fog, damp, the fiercest cold, frost, ice, and snow." Surely, great physician though he is, he is somewhat misinformed on this subject, and has not himself visited the High Alps during winter, but has possibly formed his impressions from a writer who practised during winter in Southern Italy. I shall discuss the author's objections *seriatim*, as this will show the character of the climate.

1. The "mist" and "fog" amid which he imagines the patient to be during winter in the High Alps exist, indeed, only in imagination. They are at all events excessively rare in those high valleys in winter, and when Zurich, Berne, and Basle are for days together wrapped in dense mist, the sky is most blue in the High Alps, and the air perfectly transparent and transcalent. M. Billwiller, the head of the Meteorological Department in Switzerland, has quite lately organised a system of recording sunshine at different meteorological stations, and I have, by chance, before me the comparison between Zurich and Davos, during the months of last November and January (having mislaid the number for December). At Zurich the amount of sunshine during the month of November was 48½ hours, or an average per day of 1 hour 36½ minutes; ditto at Davos, 128 hours, or 4 hours 16 minutes per day. During the month of January at Zurich the recorded sunshine was 37 hours, or 1 hour 11 minutes per day, the same at Davos, 137·8 hours, or 4¾ hours per day. All those authors who are thoroughly acquainted with the winter in the Alps, as Spengler, Waters, Frankland, Ludwig, Volland, Addington Symonds, Theodore Williams, and Jaccoud, amongst others, have described the absence of mist and the abundance of sunshine, and it is only a corroboration of their statements, when I add, that while at Zurich and in the whole of the lower regions of Switzerland a thick mist entirely shut out the rays of the sun from the 18th to the 27th of January last, 6 hours of sunshine were registered daily at Davos, and what kind of sunshine this is the dwellers in the lower regions who have never been in the High Alps during winter can scarcely imagine. At the end of November, 1869, I spent on the Piz Languard, about 10,700 feet above sea level, and on an ice pyramid of the Morteratsh glacier (about 9700 feet) more than 1½ hours on two consecutive days without an overcoat. As long as I remained in the sun I never felt warmer in August and September at the same localities, but in the shade an overcoat would have been just a comfort, though I did not feel cold in spite of a temperature of only 20° to 25° F., the air being perfectly calm. A black bulb thermometer *in vacuo* showed in the sun between 88° and 92° F., while an ordinary thermometer showed only between 31° and 32° F., and the exhaled breath became rapidly condensed. This shows that the air itself was only slightly heated by the sun's rays, though the body covered with woollen clothes had all the benefit of the warming rays. I specially mention this difference between the black bulb and the ordinary thermometer because it shows that the air inhaled is cold, to which point I shall later return. During these two days a dense mist prevailed in the lower part of Switzerland and Upper Italy.

2. How can the author call the air damp, and how has he obtained this notion? Dr. Frankland speaks of the "excessive dryness of the air at Davos," and further on says, "The absence of suspended watery particles in the air has no doubt very considerable influence in preventing the chilling of the skin." I need only consider the facts that air at a low temperature can hold only a very small quantity of watery vapour, and that if that small maximum is reached the vapour must become condensed in the shape of mist or fog, the rarity of which I have already mentioned; and the usual transparency and transcalency show likewise that the quantity of suspended vapour can be only very small. All the authors agree on this point, and Dr. Volland and Mr. Waters have further pointed out that also the air in the rooms is very dry, indeed, even drier than out of doors. Mr. Waters found the relative humidity in his bed-room at Davos during the winter 1881-82 varying from 25° to 35°; the temperature of the room being about 60° F. with an open window at night.

3. "The fiercest cold and frost" of which our author speaks is scarcely felt by the patients at Davos or St. Moritz; Spengler, Waters, Frankland, Unger, A. Symonds, Theodore Williams, Ludwig, Rohden, Peters, and myself, as well as many others, have often discussed this question. The main points which prevent the cold being much felt are:—(1) That the air is dry; (2) that it is calm; and (3) that the sun heat is very great. In an excellent article in a recent number of the *Practitioner* on "Winter Health Resorts" the same question is discussed. "The temperature of the human body depends very much on the dryness of the air. A Canadian feels it much colder at 4° below freezing-point in London than in Canada when the thermometer stood at 40° below zero. The dryness of the air in Canada more than compensates for a difference of 68°. Dry air has very little capacity for heat, so that when it is at rest it conducts away very little heat from the body." Wind changes the matter very considerably; but wind, as I have said, is rare during winter in the chief Alpine health resorts; partly through the shelter of the mountains, partly through the absence of local winds, as every place is covered with snow. In summer there is much more wind, and it is then often very disagreeable, and unless care is taken chilling; but it is not so injurious as it would be in winter. I have spoken already of the great sun heat, and the papers of Waters, Frankland, and others are well known. The result of this sunshine and absence of wind is that even rather delicate invalids can sit for many hours lightly covered on open terraces and in verandahs, or on seats, along the southern slopes of the mountains or round the ice-rink; that they can frequently drive in sledges and take short walks; while the hardier ones can join in long excursions, in skating, and tobogganing; the time passes quickly and the majority of invalids manage to be more in the open air than on the Riviera. Is the calm, dry cold of the Alpine winter health resorts injurious? My answer is decidedly, No. It is not only not injurious, but beneficial to all those who are suited to this climate. When warmly dressed, the invalids who are able to walk can be out, even if there is no sun, provided there is no strong, cold wind; and the majority of them can with reasonable precautions in dressing even walk on calm evenings. The danger of becoming chilled at the time of sunset is far less than in the Riviera climates. It is only a remnant of our old prejudice which can make us afraid of dry, calm, moderate cold. A consumptive patient is in a better condition for recovery if he lies on a couch in a judiciously selected spot in the open air even in winter than in a shut-up room. The low temperature of the air has the obvious advantage that the bacillus and other microbes cannot thrive in it, and that putrefaction is arrested. In addition to this, the low temperature of the inhaled air leads to loss of heat, and of a large amount of water. This, I presume, acts as well in an antiphlogistic as also in an antiseptic way; and it may arrest the disease by drying up a sore and by checking the thriving of the bacillus within the lungs. The diminution of the expectoration observed in many cases is partly due to it, and, perhaps, also that of the night perspiration. The pulmonary circulation becomes increased, in order to supply the water lost, and the energy of the right heart, and of the cells and tissues of the lungs, must be likewise favourably influenced. The respiratory thoracic movements cannot escape being rendered more active, and through this expansion of the thorax, strengthening of the thoracic muscles and a help to all the respiratory acts. It is not too much to say that a great part of the favourable influence of the winter climate of the High Alps takes place through the increased inhalation of this cold, dry, pure, and rarefied air.

4. I fully acknowledge the author's correctness with regard to ice and snow in the winter climate of the High Alps, but with this I find as little fault as with the calm cold air. Indeed, they are almost inseparable, for the ice and snow

which cover the ground prevent dust and decay, and the microbe laden emanations from the soil. The calmness of the air, the absence of local winds ("Thal" and "Berg" winds), are in great part due to the ground being covered with ice and snow; furthermore, where the roads are for months together covered with snow, the invalid can walk on them without the danger of wet feet, and the healthful exercises of sledging, tobogganing, and skating for the more hardy invalids and their companions are certainly not to be despised.

After having discussed the bad character of our author's Alpine winter I must devote a few minutes to the purity and rarefaction of the air. The purity, or aseptic character, is intimately connected with the cold, ice, and snow, and also with the sparseness of population and industries. To this point, and particularly to the comparative absence of spores, I had always been inclined to ascribe the favourable influence of residence at high elevations on phthisis; and when Professor Tyndall in 1868 directed my attention to Pasteur's researches, published in 1862, I became strengthened in this view, which I mentioned at the Medical and Chirurgical Society in 1869. The facts published by Miguel, and already quoted above, as to the absence of microbes in the Alps at localities above 2000 metres, strikingly show the purity of the air. I am not, however, blind to the fact that wherever a large number of human beings, especially invalids, congregate, there the purity of the air is likely to be impaired. The rarefaction or rarity of the air with which its lightness or diminution of pressure is intimately associated has been the subject of many theories; for instance, as causing a starvation of oxygen and the peculiar kind of mountain anæmia, of the existence of which, however, I have not been able to convince myself in the Alps. What seems to be certain is that more blood flows to the surface of the skin, that this organ becomes better nourished, that internal organs become in proportion somewhat unloaded, and, further, that the separation of carbonic acid from the blood in the lungs is facilitated (Marcet and Chermond). I am less certain with regard to the view that a diminished quantity of oxygen contained in a given quantity of air leads to the inspiration of a larger volume of air, and through this to a greater expansion of the lungs and thorax. This theory has been quite lately expounded in a very plausible way by Professor Jaccoud, a great advocate of the curative effect of Alpine climates, in his valuable work on phthisis, of which a good English edition by Dr. Lubbock has just been published. I am not prepared to say that this view is incorrect; but, as I have pointed out already in 1869, and in later communications on the subject, the experiments of Frankland and Tyndall on the burning of candles on the top of Mont Blanc and at Chamounix show that, although the light-giving power of the flame is much less on the top of Mont Blanc, the quantity of stearine consumed, or, in other words, the energy of combustion, is almost precisely the same as at Chamounix. This remarkable result is ascribed by the author of the experiment to the greater mobility of the atoms in the rarefied air, "making atonement for the smallness of their number by the promptness of their action." I can corroborate the experience of Dr. Theodore Williams regarding the increase of the circumference of the thorax, and especially of the diseased side of the chest in several of those cases which have shown a satisfactory progress. I am not, however, sure that this is due to the rarity of the oxygen, as the inhalation of the dry cold air already accounts for it. Whether the thinner air of high regions is unable to hold the microbes floating, and whether in this way rarefaction is a source of purity, as Miguel seems to think, I am not able to say; but this point could, I should think, be settled by experiment.

I must deny myself the pleasure of further entering into the details of the peculiarities of mountain air and mountain health resorts. The main physical features important to us are:—1. The purity or aseptic nature; the comparative absence of floating matter. 2. Dryness of the air and soil; comparative absence of mist. 3. The coldness or coolness of the air temperature and the great warmth of the sun temperature. 4. The rarefaction and low pressure of the air. 5. The intensity of the light. 6. The stillness of the air in winter. 7. A large amount of ozone. The effects on the invalid suited to such climates are—increase of appetite, improvement of sanguification and general nutrition, strengthening of the heart and circulation, raising of muscular and nervous energy, and of activity of the skin. Under the influence of such constitutional progress, which is assisted by the local action of the aseptic dry and cold air by increased ventilation of the lungs, and by compression of the diseased parts through healthy and emphysematous dilatation of the surrounding tissue, we observe a gradual improvement in the state of the lungs, leading to arrest of the disease and actual cure.

(To be concluded.)

THE RADICAL CURE OF VARICOCELE.

By HENRY LEE, F.R.C.S.,
CONSULTING SURGEON TO ST. GEORGE'S HOSPITAL.

THE difficulty of performing an operation for the radical cure of varicocele which is at once safe and effective, without any prolonged after-treatment, is evidenced by the number of different proceedings which have of late been advocated. Favourable results have been obtained by most or all of these methods where the veins have been simply enlarged; but in the severer cases, especially when accompanied by a relaxed condition of the skin of the scrotum, the benefit derived from the operation has been only temporary.

The operation which I have now been in the habit of performing for some years in such cases is as follows. The surgeon's hands and instruments are washed in a solution of carbolic acid and wiped dry. The patient is placed in a convenient position, generally on the left side of the bed, under the influence of ether. A portion of the skin of the scrotum is then pulled up and removed either by curved scissors or a knife. The longest diameter of the wound should be transverse. The edges of the wound separate to a considerable distance. The enlarged veins are rolled between the finger and thumb, and can easily be distinguished from the vas deferens. Should there be an artery of any size among the veins its pulsation can be felt, and in that case it is separated from the veins before the operation is continued. A hare-lip needle is then introduced through the wound under some of the veins, and a figure-of-8 ligature tied round its ends over the veins. The same thing is done with another needle about half an inch distant. A thin knife is then introduced on the flat beneath the veins, its edge turned towards the surface, and the veins divided. An ordinary iron cautery, previously heated in the fire, is dabbed on a wet sponge until very little steam is produced; the cautery is then applied to the extremity of the divided veins, and allowed to remain quietly in contact with them for a quarter or half a minute. The tissues adhere firmly to the iron and to each other, and the blood is firmly coagulated in the veins. In order not to disturb the parts by any unnecessary violence, the tissues are gently separated from the cautery by the handle of a scalpel. The needles placed under the veins are now removed and the edges of the wound brought together by short fine hare-lip pins, or by a continuous suture of carbolised catgut. The loss of blood in this operation often does not exceed a teaspoonful. The wound generally heals in great part by first intention. The cautery, applied as described, produces no slough. The charred surface is absorbed, as are also the clots in the veins. At the end of forty-eight hours the patient may be removed to a sofa, and may leave the house within a week.

The son of a medical man had for years been troubled with greatly enlarged veins and a relaxed scrotum, accompanied with occasional pain. He was operated upon on a Wednesday, and went down to Brighton on the following Tuesday. An officer in the army, having little time at his command, and wishing particularly to see his friends before rejoining his regiment, had the operation performed and left London within a week. In both these cases the result was most satisfactory. Details of cases might readily be multiplied.

The only inconvenience that has arisen is that in some instances a portion of the wound has been long in healing, but this is accompanied with no pain, and does not prevent the patient going about his usual avocations. It may, however, not be altogether a disadvantage to allow the wound to granulate, as the longer that action continues, the firmer will be the cicatrix. The one danger in operating for varicocele is absorption by the open mouths of the veins. If these are effectually closed a wound in the scrotum may be safely treated in the same way as a wound on any other part of

the body, and it requires no very particular attention. When a vein is divided by ligature, or if a rod-hot cautery be applied, some amount of ulceration and suppuration necessarily takes place. Both these processes are incompatible with the adhesive action, and the latter can only commence when the former has ceased. If a ligature be applied to a vein, a patient is never safe so long as it is ulcerating its way through; and the same may be said when a portion of the vein is made to slough by the application of the red-hot iron or by the galvanic cautery. The caution that surgeons have always shown in dealing with veins affords abundant evidence of the risks incurred if the veins be not completely closed. This object is effectually accomplished by the application of the actual cautery as above described. The parts are glued together before the operation is completed, a chemical adhesion of the different tissues takes place, the blood in the veins is firmly coagulated, and the vessels are securely sealed.

The removal of a portion of the skin in front of the scrotum as a remedy for varicocele was first, I believe, practised by Dieffenbach, and was advocated by the late Mr. Briggs. In an able memoir published by Dr. Henry, Surgeon to the New York Dispensary, he gives the credit to Sir Astley Cooper of having originally suggested the operation of "amputation of redundant scrotum in the treatment of varicocele." While this operation, he says, had met with much favour and been attended by successful results in New York, it has been comparatively neglected in England, Germany, and France.[1] Mr. Wormald proposed to lessen the scrotal bag by drawing a portion of it through a ring which was worn during the daytime. This is a plan of treatment not uncommon in the present day. The persistency with which patients affected with varicocele occasionally wear these rings and different kinds of suspensory bandages indicates conclusively the relief which they sometimes afford. As long, however, as the veins are left in a varicose condition, the disease cannot be cured. The practice soon, therefore, came into use of obliterating the veins by ligature, and later still by subcutaneous section. A large proportion of the cases in which the last-named operation has been performed have been permanently cured, some have been relieved, and in some the varicocele has become as troublesome as before.

The cases which have been the least successful are those in which the skin of the scrotum has lost its natural elasticity and become relaxed and redundant. The difficulty of dealing with such cases first suggested to me the plan of combining the operation of dividing the veins with that of removing a portion of the skin of the scrotum. This operation may be modified to suit individual cases, but in principle it is that which I am now in the habit of performing. The use of an anæsthetic entirely removes any objections that might be made to the use of the actual cautery on account of any pain which it might be supposed to produce in these operations. Patients sometimes, but very seldom, complain of some burning pain afterwards, but they certainly do not complain more than when the veins are subcutaneously divided. It is well that the bleeding should be completely controlled by pressure before the cautery is applied, otherwise the blood prevents the cautery from remaining fairly in contact with the orifices of the vessels. This may be the case if the iron be heated above the boiling-point of water. There is then a danger of the blood instead of coagulating being boiled, and also of the surrounding tissues being destroyed, instead of adhering to each other. The great advantage of operating with the actual cautery is that the divided vessels are completely sealed, and if the operation be properly performed no bleeding occurs, and no coagula are left in the wound. But that which is of far greater importance is that no absorption can take place through the veins. This is, in fact, the object of all antiseptic dressings. As far as any constitutional effects are concerned, lymphatic absorption is, I believe, unknown as a consequence of the operation above described.

The late Sir James Simpson was in the habit of relating how, after the American War, when he entertained some of the Northern surgeons at dinner, he told them that he believed that they had been in the habit of poisoning the wounds of the Southern soldiers who fell into their hands. The medical officers laughed at the idea; Sir James persisted, and the officers became angry. At length he explained to them that the pieces of flesh, including the divided extremities of the arteries, which were strangulated by ligatures died, decomposed, and were apt to poison the wounds. It is these decomposing particles which have necessitated the various forms of antiseptic dressing which have of late been so profusely used. But if the veins be closed, no such absorption can take place. In surgical operations where the veins can be completely sealed, as in cases of varicocele, venous absorption may be prevented with the greatest certainty.

Many years ago a patient presented himself at St. George's Hospital in whom the scrotum was so relaxed that when he lay upon his back the testes would hang over on the outer side of the left thigh. There was a well-marked varicocele. It was thought practicable to remove a large portion of the skin of the scrotum, and to obliterate the veins at the same time. Two needles were introduced under the most prominent veins far apart. Over the ends of each needle a figure-of-8 ligature was passed, so as to command any bleeding from the veins. The intermediate portion of skin, together with the subjacent tissues containing the enlarged veins, was then removed, leaving a very considerable gap. No hæmorrhage occurred. The needles were then drawn towards each other and the edges of the wound held in position. The wound readily healed, and the testis was subsequently retained very nearly in its natural position. This was the first case in which this operation was performed. Previous to that time no one thought of cutting deeper than the skin, as no means were then in use which would effectually control hæmorrhage from the spermatic veins. In the operation which I now perform the portion of skin to be removed is dealt with first, and the veins divided afterwards. The veins are sealed so as to prevent hæmorrhage on the one hand and absorption on the other, and the needles at once removed.

In cases of varicocele where the scrotum is not relaxed, the subcutaneous division of the veins answers very well without the removal of any skin. It was originally proposed to allow the needles which compressed the veins to remain undisturbed for forty-eight hours. It has since been suggested that they might be removed at an earlier period. As far as any fear of hæmorrhage is concerned, this might certainly be done; but, on the other hand, there might be a danger of the circulation through the veins being restored before their divided extremities were consolidated. In the severer cases in which the scrotum has become unnaturally pendulous, it is advisable to remove more skin than at first might appear necessary, so that that which is left may act the part of a suspensory bandage.

Savile-row, W.

[1] This operation has lately been revived in Paris.

WHAT IS THE EXPLANATION OF ACQUIRED IMMUNITY FROM INFECTIOUS DISEASES?

BY GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON, U.S.A.

(Concluded from p. 657.)

THAT full justice may be done to the "antidote theory," I quote fully from the latest authority who has written in its favour. Klein says: "There is another theory commonly spoken of as the 'antidote theory' (Klebs). According to this, the organisms growing and multiplying in the body during a first attack produce, directly or indirectly, some substance which acts as a sort of poison against a second immigration of the same organism. I am inclined to think that this theory is in harmony with the facts. There is nothing known from the observations before us which would negative the possibility of the correctness of this theory; nay, I would almost say all our knowledge of the life of the micro-organisms points to the conclusion that the different species are associated with different kinds of chemical processes, and that as a result of the activity we find different chemical substances produced.[1] The different fermentations connected with the different species of fungi afford striking illustrations of this view. According to this theory we can well understand that, just as in the case of an animal, say a pig insusceptible to anthrax, the insusceptibility being due to

[1] This is beyond dispute.—G. M. S.

the presence in the blood and tissues of a particular chemical substance inimical to the growth of the bacillus anthracis—so also in the case of a sheep or ox that has once passed through anthrax—there is now present in the blood and tissues a chemical substance inimical to the growth and multiplication of the bacillus anthracis whereby these animals become possessed of immunity against a second attack of anthrax. Whether this chemical substance has been elaborated directly by the bacilli, or whether it is a result of the chemical processes induced in the body by the bacilli during the first illness, matters not at all; it is only necessary to assume that the blood and tissues of the living animal contain this chemical substance. Some observers (Grawitz, &c.) are not satisfied with this theory, but assume, &c.[2] ..... On the whole, then, we may take it as highly probable that, owing to the presence in the normal blood and tissues of a living animal of a chemical substance inimical to the growth of a particular micro-organism, this animal is insusceptible to the disease dependent on the growth and multiplication of this micro-organism; and, further, that in those infectious maladies in which one attack gives immunity against a second attack of the same kind, one attack produces a chemical substance in the blood and tissues which acts inimically to a new immigration of the same organism; hence the animal becomes insusceptible to a new attack, or is 'protected.' This is not the case with all infectious maladies, for, as is well known, in a good many instances, a single attack does not protect against a second; and, as is also well known, a first attack may protect only for a limited period, or for a period greatly differing in different individuals. All this would be explained by our theory in the same way as it is explained by the other theories—viz., when one attack does not protect, no inhibitory chemical substance has been produced; while in those diseases in which one attack does protect only for a limited period, the necessary inhibitory substance has only lasted for a limited period, and so on."[3]

It is unnecessary to point out that Klein simply states and reiterates his own opinion in all that he says with reference to the theory which he favours, and that no experimental evidence is adduced in support of this opinion, nor, I may say, any arguments worthy of consideration; yet it would seem that, as in the case of the first hypothesis, a very simple experiment should decide whether this view is tenable. Fortunately, the experimental evidence which shows that it is untenable is at hand, and has been furnished in part by Klein himself.

It is difficult to understand the kind of reasoning which excludes Pasteur's hypothesis upon the ground that the anthrax bacillus multiplies freely in the blood of an immune animal, or in an infusion of the flesh of an animal dead of anthrax, but which supposes that a chemical poison present in the tissues prevents the development of the bacillus in the protected animal. What, then, has become of this poison when the blood of such an immune animal is drawn from its veins into a test-tube, or in the infusion made from the flesh of a recent victim of anthrax? We might possibly admit that the hypothetical chemical substance which remains for years in the blood and tissues of an immune animal, notwithstanding the elaborate provision made by nature for the excretion of useless or injurious products, is dissipated by boiling in the infusion made from the flesh of the animal; but this assumption will not apply to blood freshly drawn from its veins, which also furnishes an admirable culture-medium for the anthrax bacillus. But even this possibility has been disproved by Pasteur, who has given the *coup de grâce* to the antidote hypothesis by the following experiment. He says, "Is this the only possible explanation of the phenomenon?" referring to the exhaustion theory. "No, we may admit the possibility that the development of the microbe, in place of removing or destroying certain matters in the bodies of the fowls, adds, on the contrary, something which is an obstacle to the future development of this microbe. The history of the life of inferior beings authorises such a supposition. The excretions resulting from vital processes may arrest vital processes of the same nature. In certain fermentations we see antiseptic products make their appearance during, and as a result of, the fermentation, which put an end to the active life of the ferments, and arrest the fermentations long before they are completed. In the cultivation of our microbe products may have been formed the presence of which possibly may explain the protection following inoculation. Our artificial cultures permit us to test the truth of this hypothesis. Let us prepare an artificial culture of the microbe, and after having evaporated it *in vacuo*, without heat, let us bring it back to its original volume by means of fresh chicken bouillon. If the extract contains a poison to the life of the microbe, and if this is the cause of its failure to multiply in the filtered liquid, the new liquid should remain sterile. Now this is not the case. We cannot, then, believe that during the life of the parasite certain substances are produced which are capable of arresting its ulterior development."[4]

If Pasteur's experiment, which relates to fowl cholera only, is not considered conclusive, let us consider the tax upon our credulity which this hypothesis involves. In the first place, the individual who has suffered attacks of several different infectious diseases—as for example, of small-pox, measles, scarlet fever, yellow fever, &c.—has stored up in his blood and tissues as many distinct chemical substances as there are diseases in the list, each of which was produced by the development of a specific microbe in his body. These poisons in no way harm the individual, and no one of them, or even the combined action of several, has any effect in preventing the development of other pathogenic microbes of the same class. How different this from the action of known antiseptics, which act in a similar manner, although not in all cases in equal amounts, in restricting the development of all micro-organisms, pathogenic or non-pathogenic, of the class to which known disease germs belong. And how improbable it is that certain substances exist capable of preventing the development of these low organisms in the animal body, which are not injurious to the higher and more sensitive organism, when all our laboratory experiments go to show that the most potent "germicides" and antiseptics are poisonous agents, which are capable of destroying animal life in a relatively smaller proportion than is required for the destruction of "germs." Moreover, we are to believe that these several poisons remain indefinitely in the ever-changing blood and tissues, and that normal physiological processes, by which waste products formed in the cell laboratories of the body are quickly removed from the circulation, are impotent for the excretion of these very peculiar poisons, although non-lethal doses of potent vegetable and mineral poisons are known to be removed from the body in a comparatively short time. We are also required to believe that during the development of a vaccine vesicle in an infant a poison is formed, inimical to the development of the small-pox germ, in such quantity as to afford it protection during the period of its growth and maturity, and perhaps during a long life. In short, the difficulties in the way of accepting this explanation seem to be quite equal to those involved in the "exhaustion theory," and we are obliged to look further for an explanation of the phenomena in question.

As already stated, the explanation which seems to the writer most satisfactory, and most in accordance with the facts, is that which has been denominated the "vital resistance theory." It is well known that living tissues resist the invasion of putrefactive organisms, while dead tissues quickly fall into putrefactive decomposition. So, too, blood within the vessels of a living animal does not behave like the same fluid in a test-tube, but in some way disposes of the bacteria of putrefaction when they are injected into the circulation instead of nourishing them and being decomposed by them. Perhaps the histological elements of the vital fluid which exhibit the greatest vital activity—namely, the leucocytes—may be directly concerned in removing from the circulation bacteria which are introduced experimentally on those pathogenic or harmless organisms which by accident find their way into the blood. However this may be, it is evident that the blood and tissues of a living animal resist putrefaction by virtue of their vitality, and we are justified in using the term "vital resistance" in explaining the immunity of certain animals (acquired), or of certain races (inherited) to the invasion of certain pathogenic micro-organisms belonging to the same class as that which includes the bacteria of putrefaction, although we may not be able to explain the *modus operandi* of this vital resistance or to define exactly what vitality is. We know, at least, that vital phenomena are exhibited by a special kind of matter called protoplasm, and that the living portion of the histological elements of the blood and

[2] Already quoted, see *ante*.

[3] Op cit., p. 249.

[4] Op. cit.

tissues is composed of the complex nitrogenous substance which has received this name. We know, too, that this living matter, although apparently the same in its gross chemical and physical structure wherever found, has the most varied vital characters, which have been transmitted to it by living matter of the same kind from which it is derived. The special vital characteristics of each bit of protoplasm, enclosed in a cell wall or otherwise, are manifested during its growth, and, as is well known, certain cells—as, for example, the fertilised ovum of a mammal—develop into most complex organic structures; while others, as in the case of a micrococcus or a yeast cell, simply produce other cells like themselves. Not only are the characters which distinguish one species of animal or plant from another transmitted in this way, but individual characteristics may be transmitted in like manner, especially those of a vital or physiological order—such as a feeble or robust nervous or digestive system, a tendency to long life or to premature decay, vital resistance to morbific influences, &c.

As examples of inherited physiological peculiarities of the order last mentioned, I may refer to the predisposition in some families to diseases of the nervous system—insanity, epilepsy, and the like,—to the vulnerability of others to tuberculous infection, to the small-pox poison &c., and to the very feeble vitality of many children born of parents whose vigour has been impaired by excesses or disease, and which causes them to fall victims to the first devitalising agent with which they come in contact. On the other hand, we have numerous examples of unusual individual or family resisting power to specific morbific agents, and this is still more marked in certain well-defined varieties or races of man and of the lower animals. Thus, the negro, as already mentioned, is less subject than the white man to severe forms of malarial fever and to yellow fever; the Algerian sheep has an exceptional immunity from anthrax; the fatal form of septicæmia in the mouse, which Koch has so well studied, affects only house mice, while field mice are not susceptible to it. But, in addition to these inherited differences in vital resistance to various morbific agents, it is well known to physicians that wide differences in susceptibility to the action of these agents result from influences which lower the individual standard of vitality, temporarily or permanently. Among the most prominent of these influences may be mentioned hæmorrhage, chronic wasting diseases, excessive fatigue, inanition, venereal or bacchanalian excesses, &c. This is shown in a striking manner during the epidemic prevalence of pestilential diseases, which find their victims especially among those whose vital resistance is "below par" from one of the causes above mentioned.

The absolute immunity which certain species of animals have against the infectious diseases of other species is probably due in great part to causes of a different order, and is to be attributed to constant (specific) differences in the chemical composition of the tissues and fluids, and to differences in the normal temperature of the body, &c., which constitute favourable or unfavourable conditions for the development of particular pathogenic organisms. But this is quite a different matter from the relative immunity which results from a single attack of one of the infectious diseases, which may in certain cases be overcome by unusually large doses of the disease poison, by exposure when the general health of the individual is at a low standard—deficient vital resistance of a temporary nature,—or by an unusual individual susceptibility—"idiosyncrasy." There can be no doubt, then, that differences in vital resisting power do exist which determine the development or otherwise of a first attack after exposure to infection in those diseases in which one attack is to a greater or less extent protective; but this does not explain the immunity which follows such an attack. This I believe to be due to an increased vital resistance to the specific disease poison—probably not to the germ, but to the chemical products evolved as a result of its vital activity, and which give it pathogenic power—resulting from a tolerance to this poison acquired during the attack, when it must be present in the system in considerable quantity.

We have numerous examples of acquired tolerance to the action of known toxic agents, and especially to those which act chiefly upon the nervous system—e.g., opium, tobacco, arsenic. And there is evidence that disease poisons produce the morbid phenomena which characterise the acute infectious diseases, in part at least, by their action upon the nervous system. The febrile phenomena, for example, are no doubt largely due to the action of some toxic agent upon the nervous system; and the chemical explanation of fever, which supposes that it corresponds with the rise in temperature observed in a liquid undergoing fermentation, is as crude as is the chemical explanation of immunity. Evidently, if the explanation is correct thus far, the vital resistance of which I speak is a property of the living matter or protoplasm of the body, and resides in the cellular elements of the tissues—nerve cells, gland cells, muscle cells, leucocytes, &c. Now, these cells are not fixtures like bricks in a house, but are constantly being replaced by other cells. Their progeny, which in their turn grow old, die, and give way to younger generations. It is therefore necessary to suppose, in order that this explanation may cover the fact of a continued immunity for many years, that the tolerance acquired during an attack by the cellular elements of the body is transmitted to their cellular progeny through successive generations. This supposition will not overtax the credulity of biologists and of physiologists, for they are familiar with the wonderful power which protoplasm has of transmitting its peculiar vital properties, inherited or acquired, to its offshoots.

The vegetable kingdom furnishes us excellent examples of the transmission of acquired properties through successive generations of cells. Cultivated varieties of fruits and flowers are propagated by slips, buds, or grafts. The cellular elements of each bud or graft are in this case the direct progeny of those in the first cutting, which was selected because of some peculiarity which it was desired to propagate. But if we plant the seed produced by such a bud or slip, we do not obtain the peculiarities of fruit, flower, or foliage which we had preserved by the first mentioned method. In like manner acquired immunity from infectious diseases and acquired physiological or structural peculiarities generally are not transmitted through the reproductive elements of an individual to his offspring, at least not to an extent at all comparable with the transmission of race or family peculiarities. How, then, are these race or family peculiarities established? Darwin has answered this question in a most satisfactory manner for plants and animals in a state of nature. There are congenital differences in the progeny of the same parents which give character to the individual and which are to a greater or less extent transmitted to his offspring. "The survival of the fittest" has a constant tendency to perpetuate advantageous peculiarities, and these are intensified in succeeding generations by the action of the same general law of natural selection. It is by the action of this law that we explain acquired race immunity, as, for example, the superior tolerance of the negro to the action of malaria. Living in an intensely malarious region, a race tolerance has been established for this poison by natural selection and the survival of the least susceptible individuals. In this case we cannot explain the superior tolerance to the malarial poison by supposing that acquired individual tolerance has been transmitted and has become a race character, for the malarial poison is peculiar in that one attack not only does not protect, but constitutes a predisposition to subsequent attacks. I am disposed to explain in a similar manner the marked difference in susceptibility to infectious forms of septicæmia, which is exhibited by carnivorous and herbivorous animals. The herbivora are especially susceptible to these septic germ diseases, which are propogated by inoculation and are known to us mainly by laboratory experiments. It is evident that in a state of nature they are little liable to accidental inoculation with septic material containing the various organisms associated with putrefactive decomposition, and consequently there has been no opportunity for the establishment of race immunity by the survival of the least susceptible. The carnivora, on the other hand, are frequently forced, in a state of nature, to feed upon putrefying animal bodies, and in their battles over such prey must constantly wound each other with teeth or claws smeared with material containing septic organisms. If wolves were as susceptible as rabbits to the forms of septicæmia referred to, it would appear that the species could not long escape destruction. But this is not the case, and I can scarcely doubt that their immunity is the result of the survival of the least susceptible through successive generations; or, in other words, is due to natural selection.

MR. LEWIS W. STEVENS, L.R.C.P. Ed., &c., has been appointed a Justice of the Peace for the district of Robertson, Cape of Good Hope.

ON SOME

SURGICAL ASPECTS OF RENAL TUBERCULOSIS.

BY REGINALD HARRISON, F.R.C.S.,
SURGEON TO THE LIVERPOOL ROYAL INFIRMARY.

TUBERCULAR disease of the urinary organs has recently received considerable attention, and the literature of the subject has been importantly added to by the French school of pathologists. In reviewing urinary tuberculosis it is impossible entirely to dissociate any one part of the system as belonging to the physician, it being now well recognised that certain morbid conditions feign well-marked surgical complaints, and give rise to consequences which are only amenable to surgical interference. The observations I am about to make have been led up to by cases presenting symptom indicating the necessity to explore for calculi or to practise cystotomy for their relief.

Tubercle of the kidney in its earliest form I have frequently found to be a cause of incontinence and urinary irritability in children; many children, especially males, who were suspected of stone, proved to have tubercular kidneys. It is not easy always to determine cases of this kind. In one instance recently under observation, where in addition to medical treatment, circumcision of an elongated prepuce had been performed, extensive renal tuberculosis with almost entire atrophy of one kidney was shown after death to have taken place. In assisting to make a diagnosis between what we may call medical and surgical incontinence, I have found the use of the thermometer extremely valuable in doubtful cases. If there are tubercles in the kidney, the temperature will generally show them, provided the observations are continued for some time, in addition to other indications which it is not my province to enter upon.

Of the various operations employed for the relief of urinary affections it would be difficult to mention one that had given better results generally than cystotomy; the least favourable cases, in my experience, have been those where this operation was undertaken for symptoms traceable to tuberculosis. Of these I might instance several. The following example was a particularly interesting and an instructive one of its kind.

Some years ago a small boy four years of age came under my care at the Royal Infirmary, at the request of Dr. Little, on the suspicion that he had a stone concealed somewhere in his urinary organs. He had many of the symptoms of this complaint, but though he had been sounded several times no calculus could be felt. He was the child of distinctly strumous parents, and was singularly bright and intelligent for his age. Twelve months previously he commenced to wet his bed at night and to suffer from urinary irritability in the daytime. Occasionally very small quantities of blood had been detected with the microscope in the urine, which was invariably acid and opaque. Within two months prior to his admission the urine had been charged with mucus and granular matter containing a few pus cells of a tenacious character, efforts to expel which from his bladder produced much spasm and suffering. To aid micturition, and at the same time with the view of mitigating his spasm, he acquired the habit, which at last became constant, of pulling at his penis. He seemed, as it were, to milk away the urine and what it contained from his bladder. It was under these circumstances he came into the infirmary, when it was found necessary to give him sedatives freely. The urine, always granular-looking and opaque, now and then contained something which seemed more like the white of an egg half boiled than anything else. He was sounded, under ether, but nothing abnormal could be detected by any form of physical examination that was employed. Towards evening he was generally noted to have a rise in temperature, and there was a distinct tendency towards hectic. To alleviate the constant pain and spasm of micturition a median cystotomy was performed, but with little benefit. The spasm and vesical tenesmus still continued almost unabated. In the course of a month the child died with renal symptoms and a gradual suppression of urine. Post-mortem examination showed nothing wrong with the bladder or the urethra. The ureters were dilated and the kidneys cystic and tubercular. Some of the cysts thus formed, communicating with the pelvis of the kidney, contained thick gummy-looking mucus similar to that which was observed in a more diluted form in the urine; the cyst walls seemed to be engaged in secreting this viscid matter, which obviously with some difficulty had found its way along with the urine down the ureters. This was the explanation of the dilated ureters, the bladder spasms, and the irritability which led to cystotomy being practised. Without such an explanation it was difficult to understand how the ureters could be dilated, and yet no stricture exist in the urethra.

This case has since served to illustrate, in connexion with others of the kind not very dissimilar in history, progress, and results, at least three points: (1) That urinary incontinence or irritability in young children may proceed from renal tuberculosis; (2) that though cystotomy gives relief by allowing escape of the viscid mucoid material the tubercular cysts in the kidneys furnish when it has reached the bladder by slowly trickling, or insinuating itself down the ureters, there might in other cases of this kind be more cogent reasons for opening and directly draining the cystic kidneys, with the view of preserving what remains sound in structure as well as of preventing the constant spasm or colic which is aroused by the products of the disorganised kidney forcing a way along the ureters; (3) that such a case serves to illustrate those extremely rare cases (of which but few specimens are known to exist) where stones in the bladder have been found, wrapped up as it were in fibrous or gelatinous envelopes.

It was only comparatively recently, until I had by the kindness of Mr. Bickersteth an opportunity of carefully preserving and examining a well-marked specimen of what these tubercular cysts in the kidneys are capable of pouring along the ureters into the bladder, that I felt it possible to explain the formation of semi-fibrous stones. The best specimen I know of is in the Liverpool Infirmary Museum, and has been there referred to by me on a previous occasion.[1] "In 1873 a boy was admitted into the Liverpool Royal Infirmary, under the late Mr. Long, suffering from symptoms of stone. The child was sounded carefully, but without any evidence of stone being afforded. Death occurred in the course of a few days. On making a post-mortem examination the kidneys were found in an advanced stage of tubercular disorganisation and cystic. The bladder was small, and in it lay a calculus made up of a urate of ammonia nucleus, the size of a damson-stone, surrounded by a thick layer of soft material, consisting of mucus, fibrin, and a little gritty matter, probably phosphatic. The outer covering could be cut or torn easily, and after it had been in spirit it presented on section a laminated appearance, like the fibrinous layers found in an aneurysm. On striking the mass with a metal instrument no ring was produced; hence the impossibility of determining its existence with the sound during life." Mr. Bickersteth records a similar example.[2]

The possibility that in a strumous subject a small stone in the bladder may, as it were, be wrapped up in a fibrous sort of coat furnished by a tubercular kidney must not be lost sight of in the investigation of obscure cases of vesical stone, whether or not the explanation I have offered as to their formation be a satisfactory one.

In the diagnosis of urinary tuberculosis in the adult male, in whom this disease is frequently found between the ages of twenty and forty, the careful examination of the testes and prostate with the finger often furnishes valuable evidence as to the probability of tubercle existing in some other portion of the genito-urinary apparatus which is beyond reach. When such evidence coexists with positive signs of functional urinary irritation in some form or other, further evidence as to the cause of the symptoms is hardly requisite. In all cases where there are grounds for suspicion the testes and prostate should be carefully examined. So far as the testes are concerned, there is nothing to be said in reference to their mode of examination. With the prostate it may be observed that our generally recognised method of examining this gland with the patient on his back or side is a very imperfect one, for whatever purpose, diagnostic or otherwise, it is required. To examine the prostate thoroughly and with the least amount of discomfort both to the patient and the surgeon, the former should be placed with his abdomen

[1] The Surgical Disorders of the Urinary Organs, second edition, p. 281 (with plate of stone).
[2] Observations on Lithotomy, Liverpool Medical and Surgical Reports, vol. i., 1867.

over the end of a sofa or on a pillow over the side of a bed, with the legs slightly apart, so that the surgeon may introduce the finger into the rectum with its palmar surface downwards, the patient's abdomen being at the same time pressed backwards and towards the pelvic outlet by the weight of the body on the bed. In this way the most accurate information can be obtained by the finger respecting the size, consistence, and relations of the gland. In urinary tuberculosis in the adult male small rounded bodies like shots, sometimes softened in their centres, can be felt either singly or scattered throughout the gland. This I have often demonstrated in the wards of the Royal Infirmary in connexion with the diagnosis of urinary tuberculosis. In young male children, or in adults where the prostate is immature, and it is difficult to make out accurately with the finger, even under an anæsthetic, the consistence and boundaries of the glands, I generally examine with a slightly flattened smooth staff in the bladder; this furnishes a central point of resistance which renders it easy to detect any structural change by the finger, such as a tubercular deposit. I attach much importance to the examination of the prostate in all cases of suspected tubercular disease of the urinary organs.

Liverpool.

A CONTRIBUTION TO THE

CLINICAL STUDY OF THE LIVER VIEWED THROUGH THE URINE.[1]

BY GEORGE OLIVER, M.D. LOND.

No. I.—TEN TESTS FOR THE BILE SALTS, WITH DEMONSTRATION.

THE study of the urinary aspect of diseases of the liver is so large, and withal so full of clinical interest, that he who has mastered it merely in outline, cannot well do it justice without devoting a series of papers to the elucidation of it. I, therefore, cannot hope to do more on this occasion and at our next meeting than to provide a sketch of one department—namely, the clinical significance of the colourless central components of the bile in the urine. In this communication I will confine myself to a consideration of the tests which enable us to detect the presence of the biliary salts in the urine, leaving over for the next meeting an outline of the physiological and clinical aspects of the subject.

The urinary derivatives of the biliary salts.—The salts of the bile acids, as they exist in the bile, are taurocholate and glycocholate of sodium, the former greatly predominating. These biliary constituents are not altogether eliminated by the kidneys in the chemical forms in which they are secreted by the liver. When they reach the intestines, they are split up into taurin and glycin on the one hand, and cholate of sodium on the other. The cholate is mainly reabsorbed by the bowels, a small portion only being excreted in the fæces; while the rest is returned to the liver by the portal blood, and is, at least, in part, eventually discharged in the urine. The bile salts, as they appear in the urine, therefore, in all probability, consist of the liver-secreted salts—taurocholate and glycocholate, and of the derived salt—cholate.

The clinical tests hitherto employed for detecting bile salts in the urine are unsatisfactory.—All the works on physiology and on urine refer to Pettenkofer's test—sulphuric acid and cane sugar—or some modification of it, as the only clinical means by which bile acids are to be detected in the urine. However satisfactory this test may have proved itself in the hands of chemists, who have applied it to solutions of the bile acids extracted from the urine, it cannot, I am fully persuaded, claim an analogous position as a mode of direct testing, such as the practitioner requires, for my experience of it as a clinical test has been most disappointing. In delicacy it falls very far short of the clinical needs of the practitioner, and in reacting with other substances besides the bile derivatives—e.g., albumen[2] and other organic bodies—it is apt to mislead the observer. I can, therefore, endorse Dr. Tyson's remarks on this point: "From a perusal of almost all the text-books on Physiology, and even of numerous manuals on the examination of the urine, the student is led to suppose that the detection of bile acids, if present in the urine, by means of what is called Pettenkofer's test, is one of the easiest possible. On the other hand, nothing is farther from the truth, and the fact is that *such detection by the direct application of the elements of Pettenkofer's test to urine, or any other animal fluid, is practically impossible, even if the bile acids are present in considerable amount.* Nor have any of the modifications of Pettenkofer's test, recently announced as clinically available, proved such in my hands, even where the elements of bile have been added to the urine, except where inspissated ox-bile has been used." The italics are Dr. Tyson's.[3] I am disposed to conclude from my observations that Pettenkofer's test does not react directly with the liver-secreted salts, taurocholate and glycocholate, but only so with the derived salt, cholate. Hence, it does not indicate the presence of the biliary salts in fresh ox-bile until it has had time to decompose them, and thus to liberate cholic acid; but it reacts at once, and very decisively, after the bile has been boiled for several hours with caustic potash, a procedure that breaks up the liver-secreted salts, and furnishes the derivate, cholate. This is doubtless the reason why Pettenkofer's test reacts with inspissated, though it fails to do so with fresh bile, for the taurocholate is readily decomposed by boiling only, and the extract is an evaporation product; and, furthermore, why it rarely affords at once a distinctive reaction in jaundiced urines, which are highly charged with liver-secreted salts.[4] The test for peptones, recently introduced by Dr. Randolph, of Philadelphia,[5] may likewise be employed for the direct testing of bile salts, and for this purpose it is delicate; but is unfortunately open to the objection that it reacts equally well with the merest trace of peptone—a constituent often present in small quantity in the urine of hepatic cases, and, moreover, generally in such traces as to be detected with difficulty, and, therefore, cannot always be definitely excluded.

The proposed test is founded on a physiological reaction.—The test I employ for the direct detection of the bile salts in the urine is a purely physiological one, for it is based on a reaction which belongs to the bile itself as it flows into the intestines. When the products of gastric digestion—peptone and parapeptone—which leave the stomach in a state of acid solution, meet with the bile, they are precipitated, as a tenacious layer, all over the villi of the lining membrane of the duodenum.

A solution of the bile salts precipitates acidulated albuminous urine or urine charged with peptone.—The same physiological fact is illustrated outside the body, by acidulating—by means of citric or acetic acid—albuminous urine,[6] or urine charged with peptone, and treating it with a solution of the bile salts, or by ox-bile freed from pigment, mucin, and fat, when the proteid is precipitated. I take a sample of albuminous urine, acidulate it with a citric test paper, and add a few drops of a solution of the biliary salts, and a voluminous white precipitate is observed, just as if I had thrown down the albumen by ferrocyanide of potassium, or by potassio-mercuric iodide. But though like other precipitates of albumen in failing to dissolve when heated, when the bile salts have not been added in excess, it differs from them in this—in vanishing on the addition of acetic acid. This precipitation of albuminous matter from an acid solution is induced not only by the bile salts, taurocholate, and glycocholate, but also by their derivative, cholate of sodium.[7]

---

[1] Read before the Leeds and West Riding Medico-Chirurgical Society, April 10th, 1885.

[2] I have sometimes been led to believe that the presence of albumen retards or prevents the reaction with bile acids.

[3] Practical Examination of Urine, p. 91.

[4] Just lately I met with an instructive instance of this fact in a specimen of colourless bile extracted by aspiration from the gall-bladder of a jaundiced patient. I first of all determined the presence of a fairly large quantity of bile salts. Pettenkofer's test, however, afforded no reaction within several hours; but, after boiling a portion of the colourless fluid with liquor potassæ, the test afforded the characteristic colour change in a few minutes.

[5] THE LANCET, June 28th, 1884.

[6] Physiological writers assert that the bile only precipitates the proteid from the acid solution that enters the duodenum when in the form of peptone and parapeptone, and not when in that of albumen—as when albumen is dissolved by an acid. If this be so in the duodenum, it certainly is not so in the urine. When a solution of bile salts is added to an acidified albuminous urine, the proteid is precipitated, just as in the case of acidulated normal urine artificially charged with peptone.

[7] Observation shows there are three conditions that prevent the reaction between the bile salts and an acidified solution of albumen

Why not employ an acidulated solution of a proteid in order to detect the presence of bile salts, or the derivative of them, in the urine?—Hence, as this reaction is a thoroughgoing and decisive one, why not utilise it as a means of discovering the colourless bile derivatives that may overflow into the urine? For if these biliary constituents are present, in however small a quantity, they will surely precipitate an acidified solution of a proteid—resembling, in fact, the chyme—when brought into contact with the urine. Experiment and clinical observation have proved such to be the fact.

Acidification is a necessary condition of the reaction.—I add a solution of the bile salts to albuminous urine, and the mixture is seen to be clear,[8] but on letting fall a few drops of acetic acid into it, the albumen at once falls out of solution, and on the further addition of the acid the precipitate dissolves. Then, again, I take equal parts of an albuminous and of a jaundiced urine, and the transparency of the mixed urines is unaffected; but on dropping in a citric test-paper, a cloud of precipitated albumen collects below, with, however, this peculiarity—the coagulated albumen forms a zone just above the bottom of the tube, where, indeed, the urine remains clear, because the large amount of acid concentrated at this part prevents the precipitate from appearing there. In this case the bile salts present in the jaundiced urine precipitate the albumen, as in the preceding observation, the citric acid merely performing the same duty as when employed in the mercuric or ferrocyanic test for albumen. About twelve months ago I encountered a fact in urine-testing which at that time I could not explain, nor could I derive light either from books or from my friends: the same patient, on different days, provided me with various samples of albuminous urine, which were divisible by the action of citric or acetic acid into two classes—one set precipitating freely with the acid, the precipitate insoluble with heat, and the filtrate albumen-free; and the other set unaffected by the vegetable acid. I carbolised a good example of each kind, and set it aside, believing that the explanation would be forthcoming some day or other. On now re-examining these specimens, I find the one that precipitates albumen by the organic acid contains a large quantity of bile salts; while the other has none—or merely a little more than the trace that belongs to normal urine.[9] The precipitant of the albumen was therefore in this case also the bile salts, which remained inoperative until the vegetable acid was added.

I have lately met with several urines of normal reaction, containing albumen and bile salts, in which the proteid was precipitated by merely adding an organic acid. I show you two examples. This dark urine is a jaundiced urine containing albumen; you see how freely the proteid falls on merely dropping into it acetic acid. And this is a specimen containing an excess of bile salts, but no biliary pigment, along with albumen; and you will note in the course of a few minutes that a citric test-paper produces the characteristic zone-like precipitate, leaving the lowest part quite clear. When the precipitate induced by the organic acid is collected, washed on the filter, and dissolved in an acid (such as acetic or hydrochloric), the albumen is freely precipitated afresh by nitric acid, by the picric acid solution, and by other precipitants of albumen, so that it is albumen and nothing but albumen.

Acidified albuminous urine is a test for bile salts in the urine.—I run this diluted albuminous urine, acidified by acetic acid, over a jaundiced urine, and along the plane of contact of the urines a sharply defined white band or zone of precipitated albumen will be noted, a reaction which is indeed very striking and decisive.

(To be continued.)

or peptone—namely, (*a*) an insufficiency of acid, (*b*) an excess of acid, and (*c*) the proteid present in large quantity. The precipitate with an acidified solution of albumen or peptone, or with acidified urine containing either form of proteid, dissolves on adding acetic acid, or a citric acid test-paper, to sixty minims where the bile salts are present below a certain proportion. These facts appear to me to be interesting in connexion with the temporary albuminuria or peptonuria which is confined to the digestive periods, and with the increased elimination of albumen in chronic renal disease which takes place after meals. May not a sub-acid or a per-acid chyme, or an excess of the ingested proteid, when the bile flow is imperfect, prevent the biliary salts from precipitating—or, rather, from completely precipitating as in health—the albuminoid materials which flow into the duodenum, and thus permit the premature absorption of them?

[8] When the bile salt solution is run upon an albuminous urine, or more especially upon a normal urine charged with peptone, but in neither case acidulated, a delicate zone of precipitated proteid appears, which, however, vanishes on mixing up the solution with the subjacent urine; but the opacity is restored by a citric test-paper, or by a drop of acetic acid.

[9] This patient also on several occasions furnished me with specimens containing peptones in the place of most of the albumen. One of these I also carbolised. On retesting it, I find the peptones still present, with a trace of albumen; and on running over it a diluted solution of acetic acid, there instantly appears a beautiful thick pearly-white zone. Bile salts are present in large quantity.

REMARKS ON

NINE CASES OF DEATH BY HANGING

(SIX EXECUTIONS AND THREE SUICIDES).

BY R. J. KINKEAD, M.D. DUB.,

LECTURER IN MEDICAL JURISPRUDENCE, QUEEN'S COLLEGE, GALWAY.

(*Concluded from p. 653.*)

As far as instantaneous death and freedom from suffering are concerned, hanging by means of the long drop, with the knot of the rope under the chin, seems effective and humane; but it is not unaccompanied with the danger of decapitation. This actually occurred some years ago in Dublin in the case, I think, of Kilkenny, and was then attributed to the use of an old rope which had lost its elasticity. The ropes used by Marwood were also old and had lost their elasticity, but they were thick, I should say an inch to an inch and a quarter in diameter. That decapitation did not occur was probably due to the thickness of the rope, and more especially to Marwood's long practice, enabling him to judge pretty fairly from a look at the criminal, what length of rope should be given. Yet in one of the cases I witnessed decapitation was almost complete, and it seems marvellous that the small portion of skin by which the head was attached to the body did not give way during the hour the body was left suspended. In another most of the tissues inside the neck were torn through and only the skin left intact, so that there must have been in many cases very narrow escapes from decapitation.

I do not enter on the question or express any opinion as to whether it is expedient or inexpedient, right or wrong, that capital punishment should exist. But surely so long as the penalty of death is exacted it is the bounden duty of the State to see the provision made for executions shall be as perfect as possible, so that they may be rapid, painless, and free from the possibility of mistake. The penalty of death is the heaviest punishment the law can inflict; it is a very terrible one, not alone to the criminal, but to those whose duty compels them to witness it. That any bungling should take place or any delay occur through the inexperience or awkwardness of the executioner, or that through his avarice he should be able to dispense with needful assistance, would be to add great cruelty to the punishment; yet under the present system this is not only likely to occur, but has actually happened. There is no such thing as a public executioner for the kingdom. The sheriffs of Middlesex and London appoint one, but his appointment confers no right outside their jurisdiction. The sheriffs of other counties are not obliged to employ him, and there is no fixed scale of pay. It is simply a matter of bargaining, and a sheriff can employ anyone willing to undertake the duty, and pay whatever sum may be agreed upon. Strange as it may seem, there is no lack of competitors for the loathsome office, and there is no guarantee that a totally unfit and inexperienced person may not be selected, and wretched criminals' sufferings prolonged. It seems incredible an execution should be a matter of bargaining, to be touted for like any other trade, yet so it is. I have myself seen a letter from Marwood asking for a certificate as it would be useful to him in his business. So long as capital punishment exists there ought to be a public executioner, with properly trained assistants, a fixed scale of pay, and the sheriffs ought to be obliged to employ them and no others. Furthermore, when more than one person is to be hanged at the same time, it ought to be rendered imperative that the executioner should have a sufficient number of assistants to avoid delay. The conclusions arrived at by Dr. Haughton, in a paper read before the Surgical Society of Dublin, are in the main correct, except that the fall of ten to fourteen feet is too long. In no case I have seen was the drop more than eight or nine feet, yet in one the head was almost severed from the body.

The three cases of suicidal hanging I have to record

present some features of interest. In none of them were there any traces of insanity, nor was there anything in their manner or conduct which could have led one to suppose that suicide would be attempted. In only one could any reason for the act be traced.

E. S——, aged thirty-six, was last seen alive at about 1 P.M., when his dinner was served. At 2 P.M. he was found hanging in his cell from the gas-pipe; his feet were about six inches from the floor. The warder who found him cut the body down at once. When I saw him at 2.25 he was quite dead; the body was warm; rigor mortis had not set in. The eyes were half open, pupils moderately dilated. The face was pale and calm. The tongue was not protruded or pushed up against the roof of the mouth, nor was it dark in colour. The fingers were not clenched; surface of body pale; no evacuation of fæces or semen. He had drunk all his soup and eaten part of his bread. He had used his neckerchief as a means of suspension.

T. K——, a strongly built, robust man, aged thirty-seven, was found dead at 6 A.M. hanging by his necktie from his hammock hook. He had been seen last alive at 10 P.M. on the previous evening. When found the body was cold, and he had evidently been dead some time. The body swung clear of the floor, and fæces, evidently passed in the death-struggle, were found on the floor immediately under the body. There was no trace of seminal emission. When I saw the body rigor mortis had commenced in neck and upper extremities. The face was swollen and livid. The right eye closed, the left half open and prominent. The tongue, black, swollen, and protruded, was pressed against the upper jaw; the limbs were livid; the surface of the body was congested and the hands clenched.

T. B——, a lad aged eighteen, had been in prison only a couple of days. He ate his dinner, which was served at 1 P.M. At about 2.10 P.M., after the dinner tins had been removed, he rang his bell and was let out to the closet, where he remained about three minutes and returned to his cell. Ten minutes later the warder, on looking through the trap in the cell door, saw him standing in a curious position against the wall under the window of his cell, which was immediately opposite the door. He at once went into the cell, and found him partially suspended by one of his braces to the chain of his window. He immediately loosened the brace, took the body down and sent for assistance; when found the boy appeared to be quite dead. Professor Lynham, M.D., who lived close to the prison, was sent for at once, and on my arrival at 3 P.M. I found him endeavouring to restore animation, and making use of artificial respiration. All our efforts, however, failed. The face was pale and calm. No prominence of eyes or protrusion or alteration in colour of the tongue, nor escape of saliva from the mouth. Neither was the surface of the body congested, nor were the hands clenched. What was remarkable was the rapidity with which rigor mortis set in: the boy was last seen alive at about 2.20; the body was found partially suspended at 2.30, yet when I saw it at 3 P.M. rigor mortis had commenced in the neck. As, during efforts to restore respiration, the arms were brought down to the sides, the head and neck raised up, and when the arms were extended above the head, the upper portion of the trunk arched slightly backwards—phenomena which rapidly became more marked. The method adopted for self-destruction was peculiar. The cells are heated by hot water, the pipe passing through the cell under the window; the top of the pipe is about six inches from the floor. The window opens on a swivel in the middle, and a slight metal chain attached by one end to the top and the other end to the bottom enabled the occupant of the cell to open or close the window at pleasure. The loop of the chain hung down to the edge of the embrasure of the window, which would be about the level of the boy's neck when standing on the hot-water pipe. The prisoner's braces were made of frieze and lined with coarse calico. The prisoner had stood on the hot-water pipe with his back to wall, passed his brace round his neck and through the loop of the chain of the window; he had not tied it in a hard knot or, I may say, in any knot at all, the ends making merely the first folds of a knot. Whether he then stepped down off the pipe or slipped off will never be known, but when found he was standing on the floor, his back resting against the wall and the brace tightly round his throat. The surfaces of the brace being rough, and the sides of the loop of the chain coming close together under the strain, had prevented the folded ends of the brace yielding, and consequently it held as firmly as a complete knot could have done. Whether the prisoner really intended to commit suicide or only to feign to do so, whether he slipped off the pipe, or that, thinking the fastening would yield sufficiently to allow him to breathe, he stepped off, are conjectures. Taking the entire circumstances into consideration, I believe the intention was to make a feigned attempt, knowing that the result would be his being placed in association in charge of two other prisoners. Experience has shown that when suicide is really attempted care is taken to make secure knots. I am not aware of any case on record in which the ligature round the neck was not tied.

The scientific value of these cases is sadly deficient from the want of post-mortem examinations. The results of suicidal hanging cannot be compared with those of executions, the mode of death being so entirely different; the laceration of the spinal cord, and rupture of the trachea and bloodvessels, preventing engorgement of the lungs and right side of the heart. The appearance, therefore, of criminals after execution cannot be taken as typical of hanging in general. In two of the suicidal cases the appearance was totally dissimilar, although in both the bodies were perfectly suspended. In one, suspension could have only lasted an hour at the outside, probably less; in this case the face was pale. In the other the length of time the body was hanging was uncertain; from the position and size of the hook, and the time taken in making, and the intricacies of, the knots made on the handkerchief, by which it was attached to the hook, it was evident that it was done after daylight had appeared—that is, some time after 2 A.M. The appearance of rigor mortis and the reduction of the temperature of the body led to the presumption that it had been hanging for some hours. The former alone would have been no indication of time; as in the third case, rigor mortis was apparent half an hour after the man had been seen alive. The appearance of the face and body in this case supports the statement that the face is "more often congested, especially in those who have been long suspended."

The third case has more interest in a medico-legal aspect. It confirms the fact, already recorded, that death from hanging takes place very rapidly, even with the feet or other portions of the body resting on the ground. It shows how rapidly rigor mortis may set in and how carefully the mode of hanging ought to be examined, and the means used tested, in all cases where a body is found suspended. Although it is true that in hanging (excluding executions) the presumption is in favour of suicide, yet it may be homicidal, and further, death having been otherwise caused, the body may be suspended after death. If a body had been thus found in any other place with the ligature so incompletely fastened, the presumption would have been in favour of homicide; for *a priori* it would have appeared in the highest degree improbable that a suicide would have been so careless in the arrangement of the noose, or, if he had, it would have seemed unlikely that so incomplete a fastening—only the first fold of a knot passed through the loop—could either have supported the weight of the body, or, without yielding, have borne a strain sufficient to cause death. It would rather have appeared that after death the body had been placed in that position, and that time had failed to complete the knot. Not only was such a supposition entirely out of the question, but I satisfied myself by actual experiment that, with the material used, the arrangement was effectual; for, on placing the brace in the loop of the chain, folded as it was found, and applying a downward strain to the noose thus formed, the sides of the chain came tightly together, which, with the roughness of the material, prevented any yielding and enabled it to bear a weight equal to that of the body. In all three cases the mark of the ligature was distinctly visible on the neck.

Since writing the foregoing two more executions have taken place. In both Berry was the executioner, and his method differs from Marwood's. Although both were single executions, he had the aid of an assistant, who strapped the legs while the executioner adjusted the noose, thus materially shortening the time. Instead of leaving the rope hanging its full length, so that when the noose was adjusted it looped down behind, he coiled the slack of it up under the beam, and fastened the coil with a piece of thread, thus avoiding all possibility of the rope catching under the elbow or foreleg in any way. He also placed the loop under the left ear. In neither case did the coroner consider a post-mortem examination necessary. From an external exami-

nation I judged that the vertebræ were separated, but in neither was the separation so marked or distinct as in those executed by Marwood. The faces were deeply congested, the hands were not clenched, and rigor mortis was well marked in both when taken down one hour exactly after the drop fell. My experience leads me to believe that in addition to a proper length of drop, fracture or dislocation of the spinal column and instantaneous death are most likely to be attained by the loop being placed under the chin.

Galway.

THE TREATMENT OF

ACUTE EARACHE BY THE INJECTION OF GLYCERINUM ACIDI CARBOLICI.[1]

BY H. BENDELACK HEWETSON,
OPHTHALMIC AND AURAL SURGEON, GENERAL INFIRMARY, LEEDS.

OF late years the use of various forms in solution of carbolic acid has been so universally prevalent in modern antiseptic surgery that many, as it were, hidden virtues have, by constant familiarity with the drug, become patent, as well as that the cautionary mirages which naturally always arise on the introduction of a new drug have been paled into insignificance before the light of experience. The anæsthetic properties of the drug are now much more fully understood and appreciated than they were some few years ago, although a solution of carbolic acid, short of being caustic, was well known to have local anæsthetic as well as antiseptic properties. Any surgeon who has worked for a long time at an operation such as ovariotomy, for instance, must remember his lack of tactile power when he went to his next meal. I myself have frequently dropped my glass, my tactile corpuscles having become temporarily and locally anæsthetised from constant immersion in the solution of carbolic acid which is used for instruments. In nearly all operations (the removal of a breast, for instance) the glycerinum acidi carbolici is applied to the wound to stop the after-smarting, and this it does effectually. Then arose the application of the glycerinum acidi carbolici to the exposed nerve in toothache. The relief is absolutely instantaneous if the tooth-pulp is exposed, the patient passing from the severest pain to that of a state of bliss, which all testify to who have experienced relief from toothache. I must here, in passing, just allude to the fact that when earache is due to toothache, which it is in a large number of cases, this application of the glycerine and carbolic acid cures the earache by relieving the toothache.

It is now about seven years since a patient came to me saying that his little boy of five years of age had, within the previous three hours, developed acute earache, and that his temperature was above 100° F. The temperature had been taken by his mother, and was rising. The thought occurred to me, why not inject glycerine and carbolic acid into the ears, as it was evidently a case of inflammation of the middle ear, which would eventually end in perforation and relief, as it had in this child done several times before. I injected this solution of carbolic acid and glycerine, and, to my great delight, it acted as in toothache, almost instantly relieving the acute pain. This was done at three in the afternoon, and the next morning the boy was perfectly well, and heard nearly naturally, though not quite, as he still had a cold. The tympanum never became perforated, as it had done on previous occasions, and the temperature rapidly fell to normal. This is a typical case, and I may say that I have repeated it times without number in the same way, both in children and adults—that is, in earache and in catarrhal otitis. In all cases of this kind, at whatever stage it is applied for earache, it invariably stops the pain; and I feel sure that in many cases, even when perforation seemed imminent, the relief from the pain diminished the tension, and by its strong antiphlogistic as well as anæsthetic power perforation has been avoided. If an earache returns, as it does sometimes, where a perforation has taken place and has again closed, the application of the glycerine and carbolic acid gives great relief, and stops the tendency to recurrence to the same thing in some cases, but not in all, although it always relieves pain, and thus constitutional disturbance. In cases of earache from periostitis, either in cases of chronic otorrhœa or in uncomplicated cases of inflammation of the external auditory meatus, the relief to the pain is not so rapid; but if the carbolic acid and glycerine be allowed to remain in the meatus, then relief from pain is obtained in from ten to thirty minutes. It occasionally returns in these cases, when the solution can be reapplied with renewed benefit. By this means I am convinced, by a large experience extending over some years, that if the treatment is used early, perforation of the tympanum can be stayed in many cases. Of course the tendency to catarrh, or other causes which make a patient prone to otitis, is not the object of this paper, nor also is the after-treatment of such cases where the otitis is got rid of. I am dealing only and solely with earache, and the circumstances immediately surrounding it. I may say that I am not only relating my own experience of the treatment; but, in consequence of a paper which I read before the Yorkshire Medical Society, it has been quite generally used by medical men in the north of England who have reported their experience to me. There is one way in which it may fail to relieve pain at once, and that is in case it is poured too quickly into the external auditory meatus, when the patient has his head aside, with the lobe of the ear in its natural position. In this way the air cannot escape sufficiently freely, and a bubble of air prevents the fluid from reaching the bottom of the meatus. The proper way is to draw the lobe of the ear forcibly upwards and backwards, as in syringing the ear, to straighten the entrance to the meatus, and then allow the fluid to trickle gently down one side, whilst the air escapes up the opposite side. In cases where the meatus is very swollen at its orifice, I have injected the solution up a fine elastic catheter well covered with vaseline to promote its easy passage, and in this way I have relieved earache when it could not have been alleviated except by a hypodermic injection of morphia or such means.

I have taken great pains to arrive at the best strength of carbolic acid and glycerine to attain these results, and I find that weaker solutions do not cure the pain so rapidly or effectually. If weaker solutions are used, they will be found to fail in attaining the same results, and of course stronger solutions would soon become caustic. The glycerinum acidi carbolici in this form is not strong enough to be caustic, and can be applied in severe earache when a perforation exists quite harmlessly.

I have a further suggestion to make as to the applicability of this treatment; but I am only able to support my suggestion by a few successful cases which have come under my own observation. I refer to this application as a means of checking the disastrous otitis in scarlet fever, as well as to relieve the earache in these cases. I am very hopeful on this point; for in one or two instances where I had an opportunity of applying the glycerine and carbolic acid, when a patient first complained of earache in scarlet fever, and the membrana tympani had begun to redden, the relief to pain was immediate, and no perforation took place.

I make the suggestion, and hope all who have the opportunity will try it, since one important (very important) element, I take it, to anyone, much more to a patient in high fever, is the immediate relief from local pain, which must act as a beneficent element in assisting the patient through his illness.

[1] A paper read before the meeting of the International Otological Congress, Basle, Switzerland, September, 1884.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—A quarterly court of the directors of this Society was held at 53, Berners Street, on April 8th, Mr. Tegart, V.P., in the chair. Six new members were elected, and the death of one reported. Applications for grants were read from sixty-three widows, nine orphans, and three recipients of grants from the Copeland Fund, and a sum of £1349 was recommended to be distributed among them at the next quarterly court. A fresh application for grants was made by a widow on behalf of herself and daughter, and grants were made them. Mr. Henry Lee and Mr. Cooper Forster were nominated for election as vice-presidents at the annual general meeting, in the place of Mr. Cæsar Hawkins and Sir Erasmus Wilson, both deceased, and the following gentlemen were named as directors to fill the vacancies arising from the retirement of the six senior, and from the death and resignation of others—viz., Mr. Hogg, Dr. Burker, Dr. F. Roberts, Dr. Broadbent, Dr. Ogle, Dr. Duka, Mr. Bennett, Mr. J. S. Turner, Mr. Stokes, and Mr. Latham. The annual general meeting was fixed to be held on May 20th at 5 p.m.

ST. THOMAS'S HOSPITAL.

A CASE OF LITHOTRITY; REMARKS.

(Under the care of Mr. CLUTTON.)

THE following case of lithotrity with prolonged manipulation is a good example of the method of procedure introduced by Bigelow in the year 1878, which he prefers calling litholapaxy, but which retains the name of lithotrity in this country. In this case the amount of débris produced was such as to render its removal at one sitting impossible, without exposing the patient to unnecessary risk, the remainder being removed seven days later without any inconvenience having resulted to the patient in the meanwhile, whilst the good effect of the first operation was well marked. The stricture, which had been carefully dilated, does not appear to have interfered with the progress of the operation, nor to have caused after-trouble.

R. R——, a coachman, aged forty-nine, was sent to Mr. Clutton by Dr. Phillips of Bromley, Kent, in the autumn of 1884. For eight months he had suffered from frequency of micturition; and during the latter part of this time had begun to feel pain at the end of the penis after emptying his bladder. The frequency in passing urine troubled him as much during the night as in the daytime; so that it is open to question whether this particular symptom was not due to the presence of a stricture from which he had suffered, for fourteen or fifteen years. He had of late neglected the stricture, and thought that all the symptoms were due to this neglect. He had during the last three or four months noticed blood occasionally in his urine, which had at the same time become thick and ropy. The pain at the end of the penis and an occasional presence of blood in the urine made it probable that there was also a stone in the bladder. A No. 6 silver catheter was with difficulty passed through a stricture at about four inches from the orifice of the urethra. A small-sized sound was then introduced, and a vesical calculus detected. He was therefore admitted at once into the hospital. In the course of a fortnight the stricture had been so far dilated as to admit a steel sound of the size of No. 30 of the French scale. But the symptoms of irritation in the bladder had been much aggravated. He was passing urine almost every half hour, and had to keep a "slipper" constantly in bed. There was also a large quantity of pus and mucus in the urine that he evacuated. It was determined, therefore, at once to give him relief by lithotrity.

On Oct. 15th, 1884, the patient being brought under the influence of an anæsthetic, a Bigelow's lithotrite was introduced and the stone seized. It proved to be about two inches in diameter, but of soft and crumbling consistence. It was therefore very easily crushed, but the amount of débris produced was so large, and the stone had broken up into so fine a powder, that even at the end of an hour and a half a considerable amount was known to be left behind. The weight of the fragments removed at the operation after careful drying was 659 grains, or a little over an ounce and a half; but no great care was taken to preserve all the fluid that came away, so that a good deal of the fine powder was lost.

On the 17th, two days after the operation, he said that he felt better than he had done for some months. He had no pain except some slight scalding in passing urine, and this was accomplished about once in two hours, instead of every half hour. Altogether the relief was very great. The urine also was quite clear, containing only a few fragments of the crushed calculus.

On the 22nd an anæsthetic was again administered and the bladder washed out by Sir Henry Thompson's improved evacuator and a No. 18 cannula, which had been used at the first operation. The second operation lasted about three-quarters of an hour, and the fragments, dried and weighed, amounted to 336 grains. The bladder was again washed out in the same way on the 30th, but very little débris indeed came away.

The patient left the hospital perfectly well on Nov. 4th. The stone was entirely composed of phosphate, and therefore very light for its size; but when thoroughly dried, the total weight of the fragments removed by the evacuator, with those passed in the intervals, was 1026 grains, or 2 oz. 151 grs. The original calculus must therefore have been of considerable size.

Remarks by Mr. CLUTTON.—This case is of interest on account of the large size of the stone, the few symptoms to which it gave rise, and the very short time that these symptoms had existed. There was, moreover, a stricture of the urethra, which increased the difficulties of the case.

LIVERPOOL ROYAL INFIRMARY.

CASE OF DISLOCATION OF THE SHOULDER, REDUCED AFTER ABOUT SEVEN WEEKS, AND FOLLOWED BY ANEURYSM (SUBSCAPULAR?), TREATED SUCCESSFULLY BY LIGATURE OF THE SUBCLAVIAN; REMARKS.

(Under the care of Mr. RUSHTON PARKER.)

THIS case is very interesting as an illustration of a rare accident following the reduction of dislocation of the humerus. The patient was not of an age when one expects degeneration of the vessels, and the dislocation was a comparatively recent one, apparently requiring no excessive force for its reduction. The aneurysm probably followed laceration of the dorsalis scapulæ artery, as suggested by Mr. Parker, and this may possibly have been injured at the point where it turns round the axillary border of the scapula, at which point it would be most exposed to injury during the necessary manipulations.

A woman, aged thirty-six, fell and injured her right upper limb in the first week of December, 1882. To the medical man who attended her she only complained of her forearm, in which he found a fracture, and treated it successfully. Four weeks later, her forearm being nearly well, she went to the Liverpool Royal Infirmary, complaining of her shoulder and general lameness and pain in the limb. On examination the head of the humerus was found dislocated, the limb somewhat œdematous, and the injured forearm satisfactorily healed without deformity. After two attempts at reduction under ether, with the heel in the axilla, by Mr. Harrison's house-surgeon, the case was placed under the care of Mr. Rushton Parker, who is indebted to Mr. Harrison for the opportunity of attending it. Again, under ether, reduction was attempted on Jan. 23rd, 1883. The patient was laid on the operating-table, having a roller towel passed round her chest on the affected side, and looped at the other end to an adjacent iron post, being put on the stretch between. This maintained her fixed while the limb was submitted to linear extension at an angle of about 60° from the trunk. At first the hands of those employed slipped off the œdematous limb, on which another roller towel was hitched on the limb, and steady traction kept up by three or four students, while Mr. Parker directed their movements, clasped the head of the bone, and kept it outwards, while the arm was brought to the side. After prolonged efforts, without any jerking, the bone was found replaced in its proper situation without any indicating sound or perceptible movement at the moment of reduction. The wrist was slung to the neck, with the elbow flexed, and the patient was put to bed. Some ecchymosis resulted and pain in the shoulder, neither more nor less apparently at first than at the previous attempts. But the pain continued; and on viewing the shoulder from time to time to ascertain the cause, there was noticed on Jan. 29th a pulsating swelling over the axillary border of the scapula behind. The pulsation was distensile; the swelling evidently communicated directly with an artery, and its size was about that of a small walnut, with additional induration around. The radial pulse was unaltered on this side, and during the period in which it was examined the position of the aneurysm was more and more conspicuous at the border of or outside the axilla, and near the situation of the dorsal scapular artery or the subscapular at the junction of the two. The swelling under rest in bed did not show any sign of diminution, but rather of increase; it was attended by severe neuralgic pain, that greatly distressed the patient,

who could hardly sleep. At a consultation with his surgical colleagues, Mr. Parker's proposal to tie the subclavian artery was agreed to. This was accordingly done on February 16th, 1884, under ether, with Lister's carbolic acid method and a chromicised catgut ligature. After the skin incision and the closure of its vessels, the fascicæ were divided with two pairs of dissecting forceps, the successive apertures being held open by Mr. Harrison with a pair of artery forceps in each hand. The artery was too deep to thread the aneurysm needle after passing it, so the needle had to be withdrawn and passed threaded. Pulsation ceased at once on compressing the artery against the finger with the ligature, so the latter was tied, cut short, and the wound sewn and drained, being covered with a Lister's gauze dressing. Union by first intention resulted without inconvenience or complication. The blood tumour that had pulsated remained for weeks unreduced in size, and felt so soft that Mr. Parker was tempted to aspirate it. This failed, as the blood was clotted, though soft. Eventually a puncture was made on March 10th, under a stream of carbolic lotion, and some black clot squeezed out. Decomposition eventually occurred, but was quickly corrected by carbolised washing, and entire cicatrisation resulted. The patient was kept in hospital all the summer, her arm being slung the whole of the time, and the stiffness of the shoulder gradually becoming slacker. She was lost sight of, and when sought in April, 1884, could nowhere be found.

Remarks by Mr. PARKER.—Six weeks after an accident one would hardly expect reduction to be so difficult as in this case. The parts were, no doubt, stiffened by the previous attempts, and all rendered difficult by inflammatory stiffening, which may have resulted from her own neglect of the injury, due to her ignorance of its existence and the omission of remedial precautions. The pulsating blood-tumour was a good example of circumscribed traumatic aneurysm that results from arterial rupture subcutaneously. It certainly did not appear to communicate directly with the axillary trunk, and was thought likely to be subscapular or dorsal scapular both from position and behaviour. Under any circumstances this must be a rare situation for aneurysm, though perhaps more likely to follow a stab than any other predisposing cause.

THE FRENCH HOSPITAL.

DISLOCATION OF THE FOREARM, OF EIGHT WEEKS' STANDING; REDUCTION; REMARKS.

(Under the care of Sir W. MAC CORMAC.)

FOR the following account we are indebted to Mr. Alfred S. Gubb, resident medical officer.

Léon P——, aged twenty-four, a musician, on Dec. 23rd last, was returning home late at night, carrying a parcel in each hand, when he was assaulted and knocked down quite unexpectedly. On rising he found himself unable to use his right arm, and any attempt to move it was attended with much pain. The next day he went to a neighbouring hospital, the arm being then very much swollen, where the case was diagnosed to be one of fracture just above the elbow-joint, and the limb was put up in an external angular splint reaching from the shoulder to the wrist. He returned to the hospital several times subsequently, but the arm was left undisturbed, until, being dissatisfied, he went on Feb. 9th to the French Hospital, where the splints were removed and the limb examined by Sir William Mac Cormac, who found a dislocation of both bones of the forearm backwards and slightly outwards. The patient was put under an anæsthetic and the adhesions broken down by flexion and extension movements, and efforts made to reduce the displacement by these and counter-extension. It was, however, only after three-quarters of an hour of very energetic manipulation that reposition was effected. The limb was then put up in fully flexed position, and secured by a plaster-of-Paris bandage. A good deal of swelling and pain followed, which were subdued by the continuous application of the icebag and the administration of opium. The limb was left in this position for a fortnight, and then passive movements were cautiously resorted to. A good deal of stiffness of the elbow and fingers remained, but after another fortnight of massage and passive movement the patient was enabled to extend the arm about forty-five degrees beyond a right angle, and to use his fingers with some amount of comfort. He left the hospital for Paris with every prospect of a useful limb.

Remarks by Sir WILLIAM MAC CORMAC.—Dislocations of the elbow are rare in adults, and in this case the interval was nearly the limit at which a successful reduction can be accomplished. Further, it serves to illustrate the difficulty of diagnosis in injuries to the elbow when the relations of the part are concealed by swelling.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Aneurysm of Abdominal Aorta treated by Distal Compression.—Localisation of Motor Centres in Spinal Cord.

AN ordinary meeting of this Society was held on Tuesday last, Dr. George Johnson, F.R.S., President, in the chair.

Mr. T. R. LUNN and Dr. F. L. BENHAM read a paper on a case of Aneurysm of Abdominal Aorta treated by Distal Compression. The patient, a man aged thirty-two, a shoemaker by trade, was admitted into the Marylebone Infirmary, in October, 1883, with a large abdominal aneurysm. He had been in the army nine years, and had syphilis five years ago. There was no history of strain or injury. The urine contained a slight trace of albumen. The patient was not relieved by the usual remedies, including rest, low diet, narcotics, &c. He was evidently getting worse, and was extremely anxious to have some operation done, the danger attending which was explained to him. On October 31st the patient was placed under the influence of chloroform, and compression of the abdominal aorta just above, and to the left of, the umbilicus was kept up four hours and three-quarters with Carte's tourniquet. There was slight vomiting on the first and third days after the operation (apparently due to the morphia and chloroform combined), but otherwise the patient expressed himself as feeling better; the tumour was smaller, harder, and pulsation less marked. The man continued to do well for seven days, but on Nov. 8th persistent vomiting set in, chiefly of a dark grumous material. The pulse was feeble, 192; there was intense thirst, no abdominal distension or pain, some dulness over right lung, the face was congested, and the feet warm. The patient became worse, and died on November 10th, the eleventh day after the operation, At the autopsy the aneurysm was found to be cured, but there was gangrene of about two feet of the jejunum.

Mr. HENRY MORRIS contributed a paper on a case of Gangrene of the Right Lower Extremity, due to an aneurysm which was full of laminated clot, and therefore practically cured. The patient was a man aged thirty-eight, who on December 27th, 1884, suddenly felt, whilst walking, severe pain, numbness, and pricking in the right leg, accompanied by profuse sweating; the left leg was also affected in a less degree, but the mobility and sensibility of the left lower limb returned, though the right remained paralysed and without sensation. On January 1st the patient was admitted into Middlesex Hospital. There was a history of syphilis sixteen years previously. Six months ago he had had lumbago, and later on drowsiness and throbbing of the right temple. On admission there was gangrene of the right lower limb; the femoral artery could not be felt. Some weakness and coldness of the left foot were present. On the right side of the abdominal parietes the veins were greatly distended. It was decided to wait before amputating the gangrenous limb. On January 14th the right limb was amputated through the lower third of the thigh by the circular method; a feeble, tiny stream of blood flowed from the superficial femoral artery. The eighth day after the operation the man died; delirium and diarrhœa had been present, and the urine was albuminous. At the autopsy the intermuscular planes of the stump were infiltrated with badly smelling sanguineous fluid. There was an infarct in the liver, and this organ weighed 71 oz.; the kidneys were swollen, and weighed 7¼ oz. each; in the right kidney there was an infarct. Atheromatous patches were present in the aorta, and an oval aneurysm, full of laminated clot and two inches and a half in length and of the size of a Tangerine orange, was found close to the superior mesenteric artery, which, however, was not involved. The bodies of the first and second lumbar vertebræ were eroded. The blood-clot extended into the aorta. Just above the right profunda artery there was an embolus. The vena cava inferior was completely blocked, as were also the

common iliac veins. The case was brought forward chiefly to show that even an aneurysm which had been cured by nature could by accident cause the death of the patient.

Mr. R. BARWELL said that it was unfortunate that the paper should have confounded proximal and distal compression for the treatment of abdominal aneurysm. There were now four cases of treatment by distal pressure; in two no benefit and no injury resulted. In Mr. Bryant's case the intestinal injury was the cause of death, just as it was in Mr. Lunn's case. He doubted whether the soft spongy clot occurred as the result of pressure, or as the result of arrest of the circulation during the last moments of life.—Mr. BRYANT said that in his case of distal compression he thought he could, with justice, attribute the clot in the aneurysm, not to a recent formation, but to one which had been formed slowly during the compression of the aorta. He considered that Mr. Lunn's case was an encouraging one for the treatment advocated. He asked for further particulars as to the precautions which were taken in applying the tourniquet.—Mr. T. HOLMES said it was open to doubt whether the treatment ought to be described as distal pressure; for there was but little space between the terminal portion of the aneurysm and the bifurcation of the aorta; it was more likely that there was direct compression of the aneurysm. He thought that distal compression was not likely to cure the aneurysm, but more likely to kill the patient. There were so many sources of collateral circulation that a cure was almost impossible. The risk of rupture of sac was great. He was inclined to think that in Mr. Lunn's case there was a genuine tendency to the cure of the aneurysm, for it had the appearance of being firmly consolidated; but he thought that this consolidation was not the result of distal pressure on the aorta.—Mr. HULKE concurred with the remarks of Mr. Holmes, and doubted whether the exact seat of the pressure could be definitely asserted, even when it was supposed to be applied proximally. In two out of three cases which had been under his observation there was direct pressure on the aneurysmal sac. The result in all his cases was successful, and the aneurysm was consolidated. Nevertheless, the dangers were great, and considerable risk must be run.—Mr. H. MORRIS spoke of a valuable contribution to the subject made by Mr. Barwell to "Ashhurst's Encyclopædia of Surgery." There were ten cases in which proximal pressure had been used, with recovery in five cases and death in five cases. Death was due to bruising of the intestine and peritonitis. It was a question as to how far the intestinal injury was due to direct pressure on these structures or to embolism of the superior mesenteric artery. He would like to know what chance there would be of gangrene of the intestines when the superior mesenteric artery was occluded. We had to do with the same dangers whether proximal or distal pressure were employed. He spoke on a subject to which he had already drawn attention—viz., that aneurysms may be cured by nature and yet bring about the death of the patient. His own case proved this, as did also a case of aneurysm of the ascending aorta in which consolidation had taken place; but a minute rent formed, through which leaking into the pericardium took place and caused death.—Mr. JONATHAN HUTCHINSON doubted whether medical treatment was wholly powerless to cure cases of abdominal aneurysm situated high up on the aorta. He referred to a case of his reported in "Holmes' System of Surgery," in which the free administration of diacetate of lead to the degree of producing a blue line on the gums and lead colic was carried out, together with the use of ice-bladders over the abdomen, a dry diet, and absolute rest. In this case within three months there was a complete cure, and the man went to work. He agreed with Mr. Holmes that there was a very great risk of causing the death of the patient by the method of distal compression. In ergot of rye, diacetate of lead, and iodide of potassium we had powerful drugs which might be used in combination, and which were able to exert a very important influence on the state of the blood and arterioles.—Mr. J. R. LUNN, in reply, said that before the tourniquet was applied the bowels were thoroughly emptied, and the bladder also. Gradual pressure was made after the skin and tourniquet had been properly dusted with powder. Carte's tourniquet was a very convenient one. The patient was a most restless man and difficult to keep at absolute rest, though this and large doses of iodide of potassium had been attempted for a period of one month without benefit.—Dr. BENHAM, in reply, quoted some references to prove that embolism of the branches of the superior mesenteric artery could cause gangrene of the intestines. He was of opinion that the pressure of the tourniquet was distal and not immediate.

Dr. C. E. BEEVOR read a paper on two cases illustrating the Localisation of Motor Centres in the Brachial Enlargement of the Spinal Cord. The first case was one of progressive muscular atrophy, occurring in a goldbeater and lamplighter, aged thirty-eight. The disease commenced three years ago, with gradual wasting and loss of power, beginning in the muscles of the back of the right forearm, the muscles of the hand and the interossei, and involving other muscles of the right arm. The left arm was affected a year later, with difficulty of supinating the forearm, flexing the elbow, and abducting the shoulder-joint. The legs have been weak for the last six months. At present the muscles most affected on the right side are the small muscles of the hand and interossei, the flexors and extensors of the wrist and fingers, the teres major, serratus magnus, deltoid, biceps, brachialis anticus, supinator longus, rhomboid, and teres minor. On the left side the same muscles are affected, except the small muscles of the hand and the flexors of the fingers; while, in addition, the clavicular part of the pectoralis major are slightly affected, and the supra- and infra-spinati are involved. The second case was that of a young man aged eighteen, suffering from infantile paralysis. The onset was sudden when the patient was a year old, with paralysis of all four limbs, of which the legs and right arm have recovered fairly well, while the left arm has remained more paralysed. At present, in the right arm, the only muscles affected are the latissimus dorsi, triceps, and pectoralis major, the sternal part of which is absolutely gone. On the left side, in addition, the teres major, subscapularis, rhomboid, supra- and infra-spinati, and teres minor are severely affected; while the extensors of the fingers, serratus magnus, and deltoid are only slightly involved. There was nothing of great importance in the course of the two cases; but they were brought forward to illustrate clinically the groups of muscles found by Professors Ferrier and Yeo to be thrown into action by faradising the peripheral ends of the divided anterior motor roots forming the brachial plexus. These groupings were shown in some tables, and side by side with them were given the muscles found to be affected in these two cases. On comparing the cases, it will be seen that whereas in the case of progressive muscular atrophy the groups of muscles severely or completely affected belong chiefly to the fourth, fifth, and eighth cervical and first dorsal nerves on the right side, and mainly to the fourth and fifth cervical nerves on the left side, in the case of infantile paralysis the opposite holds good, for on the right side the only muscles affected (the triceps latissimus dorsi and pectoralis major) are innervated, according to Ferrier and Yeo, only by the sixth and seventh cervical nerves, whilst the rest of the groups are unaffected; and on the left side the sixth and seventh cervical nerves are most affected, and also some muscles innervated by the fourth and fifth cervical are partially paralysed. The reaction of the muscles to electricity (faradisation and constant current) has been ascertained, and they correspond to the degree of power lost and to the amount of wasting, and are quite in accordance with the above groupings. A third case of infantile paralysis was also described affecting the muscles of the right arm, corresponding to the sixth and seventh cervical only—viz., teres major, latissimus dorsi, subscapularis, pectoralis major (sternal half), triceps, and serratus magnus. It should be remarked that Ferrier and Yeo's experiments were made on the motor roots, but it is considered that the groups of muscles thereby differentiated can be equally applied to the cells of the anterior cornua supplying these nerves, and these cells are known to be affected in progressive muscular atrophy and infantile paralysis.—Dr. HUGHLINGS JACKSON said that Dr. Beevor's observations were an example of a kind of work that was much wanted. Ferrier's experiments gave us some clue to the nature of the mixing up of the nerves at the level of the lowest centres. Lesions of the cervical region of the spinal cord were known to have an influence on the pupil. In these cases the pupil was small and unable to dilate when the eye was shaded. Stabs of one half of the cord illustrated this, as did also cases of rupture of the brachial plexus. Ferrier's experiments were more definite in this regard, for they showed that it was only the second dorsal motor root in the monkey which contained the dilating fibres of the iris. Stimulation of this root causes dilatation of the pupil and contraction of the intrinsic

muscles of the hand. In a case of progressive muscular atrophy under his care the intrinsic muscles of the hand were affected, and there was smallness of the pupil on the same side, and inability of the pupil to dilate when the eye was shaded, thereby affording a clinical corroboration of the experimental work. A case of Mr. Rivington's also bore out the same fact.—Dr. FERRIER said it was important that his and Yeo's experimental observations had been corroborated and verified by clinical research of so laborious a kind as that which Dr. Beevor had undertaken. The intricate plexiform arrangement of the brachial and crural nerves had long been a physiological puzzle, and his experiments were undertaken with a view to clear up the mystery. He and Yeo had found that each root of the brachial plexus of the monkey answers to a distinct and well-defined muscular action due to coördinate contractions and relaxations of groups of muscles. It was most probable that centres of complex coördination existed in the brachial enlargement of the spinal cord. Stimulation of the cervical nerves going from the upper part of the brachial swelling gives rise to a combined and coördinate movement in which the deltoid, biceps, brachialis anticus, and supinator longus muscles took part, as in the act of raising the hand to the mouth. He referred to some observations in human anatomy made by Dr. Cunningham, which showed that twenty-seven out of thirty-seven subjects examined the second dorsal nerve sent a contribution to the brachial plexus. If this relation were found to hold good, then there would exist a complete harmony between the nervous relations of the brachial plexus in man and monkey. It was important to decide whether the nuclei of all the muscles were present in each segment of the brachial swelling or whether they were arranged in a linear order. In his opinion the facts of anterior poliomyelitis seemed to show that in each segment we have the nuclei of all the muscles. Neurologists had come to recognise an upper arm type and a lower arm type, and he believed that there were as many distinct types as there were groups of muscles. In the middle of the brachial enlargement there was a coördinating centre which presided over the latissimus dorsi and pectoralis major and the rotators of the shoulder-joint. It was highly probable that in the spinal cord there were mechanisms for the carrying out of complex coördinate actions, and he believed his experiments had roughly mapped out the chief of these mechanisms.—Dr. BREVOR said that in one of his cases the right pupil did not dilate when shaded, and so resembled the instance of which Dr. H. Jackson had spoken. In this case the first dorsal nerve supplied the group of affected muscles, and therefore still further corroborated the views of Ferrier.

CLINICAL SOCIETY OF LONDON.

Amputation at the Hip-joint.—Pityriasis Circiné.

AN ordinary meeting of this Society was held on April 10th, Mr. Thomas Bryant, F.R.C.S., President, in the chair. There was a well-sustained discussion on the surgical papers.
